AGRADECIMENTOS

Marina Kirsch, agradeço pelo amor, paciência, suporte, companheirismo, *coaching*, silêncio, carinho, amizade e inúmeras outras faculdades morais relacionadas a ti. Te amo. Tu és meu maior tesouro.

Agradeço ao afeto silencioso de meus filhos felinos, com muito amor: Oby Fabiane e Charlly.

Agradeço ao meu orientador, Faridão, pelo suporte intelectual e logístico dado a este trabalho e pelos sábios conselhos e puxões de orelha relacionados à vida profissional e ao *Homo geologensis*.

À minha mãe, Bernadete, por ser sempre um exemplo de força de vontade, superação e amor Ágape. Obrigado por ser minha mãe.

À grande amiga (e poderosa chefona) Ariane Santos da Silveira, agradeço teus conselhos sobre a vida e ao teu suporte *Giganewtoniano* à minha carreira profissional.

André e Bruna, meus queridos irmãos, obrigado pelo amor e carinho. Sei que sempre posso contar com vocês. Nossas diferenças nos fazem mais fortes. Amo-os.

À família Kirsch Ohlweiler (e agregados), minha família em lei, Ana, Raul, Claudio, July, Augusta, Débora, Jessé, Bruno, Songa, Nina, Chico, Filó e Boris, obrigado pelo amor.

Agradeço aos meus antepassados.

Aos meus colegas de trabalho Zeca, Gustavo, Vanessa, Fran, Felipe, Lucas e Dante, obrigado pela paciência.

Aos amigos de longa jornada, direto do grande reino: Rafael, Duko's, Paulu's, Ananá e Marlon. Nenhuma noitada foi em vão.

Aos geólogos de peso (em termos de massa) Tiago Girelli e Henrique Serratt pelas discussões sobre o estado da arte, métodos, aquisição de dados e (principalmente) pela amizade.

Agradeço a equipe técnica dos laboratórios de DRX-UnB e Microsonda eletrônica-UnB em especial a Isabella e Gabriela. Obrigado pela paciência!

Ao pai Walmor, obrigado pelos 23 pares de cromossomos.

Aos professores e colegas da UnB.

RESUMO

Mateus Rodrigues de Vargas, 2019. Estudos Petrológicos do Complexo de Maurice Ewing Bank. Dissertação de Mestrado, Programa de Pós-Graduação em Geologia, Universidade de Brasília, 167 pp. Data 17/05/2019. Orientador Farid Chemale Júnior.

A evolução do Rodínia ainda possui diversas questões que permanecem incógnitas, afetando diretamente as interpretações paleotectônicas dos eventos geológicos contemporâneos e posteriores. Este é o caso, por exemplo, do papel da crosta Mesoproterozóica não aflorante ou, ainda, de terrenos remanescentes como Maurice Ewing Bank e suas relações com o evento formador do Rodínia. Este trabalho visa refinar, definir e interpretar as rochas do Complexo de Maurice Ewing Bank (CMEB) com aplicação de estudos petrológicos e geoquímicos. Para assim definir sua trajetória de recristalização/deformação, comparar CMEB com as principais unidades da orogenia de Natal-Maud e tecer considerações sobre os blocos envolvidos no processo. CMEB consiste de um terreno metamórfico polifásico com três ciclos de recristalização. O ciclo formador do Rodínia (R) tem um episódio de deposição e quatro episódios de recristalização e/ou deformação progressiva identificados: [1] deposição de paraderivados, em ambiente de back-arc, próximo à área fonte (R0); [2 e 3] período de longa exposição à alta temperatura e pressão, relacionado com cinturão de cavalgamento e dobramento (R1 e R2); [4] fim do evento colisional, caracterizado pela ocorrência de granitóides pós-orogênicos (R4). Nós interpretamos que R1 e R2 coincidem com a mais velha idade adquirida nos granitóides sin- a tardi-deformacionais de 1068 ± 28 Ma. Um evento de exumação tectônica, em R3, é relacionado com a idade dos granitóides sin- a tardi-deformacionais em 1032 ± 12 Ma. Subsequentemente, o evento R4 é relacionado com delaminação crustal em 1006 ± 13 Ma. O reset nos sistemas Rb-Sr e K-Ar foi gerado por um ciclo metamórfico posterior, na facies Xisto Verde. Nós o interpretamos como causado por anomalias termais distais associadas com eventos Neoproterozóicos-Paleozóicos como orogenias Panantárticas-Panafricanas-Gondwanides. O ciclo anquimetamórfico, abaixo de 300°C , é relacionado com eventos ainda incompreendidos de rifteamento na região, de idade Juro-Cretáceo. CMEB, na transição Meso- Neoproterozóico constitui a frente deformacional da orogenia Natal-Maud, estando entre dos terrenos Margate e Heimefrontfjella. Sugerimos que a colisão entre os crátons de Kaapvaal e Coats-Patagônia geraram não somente as rochas Mesoproterozóicas de Dronning Maud Land Oeste, mas também as de CMEB, Província Natal, Complexo de Cape Meredith e as rochas que geraram a anomalia de Beattie-A. O bloco de Patagônia consiste de apêndice entre Laurentia e Coats-Land. Portanto, a orogenia de Natal-Maud deve ser considerada como Grenviliana.

ABSTRACT

Mateus Rodrigues de Vargas, 2019. Petrological Studies of Maurice Ewing Bank Complex. Master Thesis, Programa de Pós-Graduação em Geologia, Universidade de Brasília, 167 pp. Date 05/17/2019. Thesis Advisor: Farid Chemale Júnior.

The evolution of Rodinia still have several questions that remain *incognito*, which directly impact the paleotectonic interpretation of coeval and posterior events. That is the case, for example, the role of either the unexposed Mesoproterozoic crust or remnant micro-terranes such as Maurice Ewing Bank and its relationship with the Rodinia-forming orogens. This works aims to characterize and interpret the igneous-metamorphic basement of Maurice Ewing Bank Complex (MEBC), using petrology and geochemistry. Thereby defining their recrystallization/deformation time path, comparing with the main units from Natal-Maud belt orogeny, and extrapolating the blocks involved in the regional metamorphism process. MEBC consist of a polyphasic metamorphic terrane with three recrystallization cycles. The Rodinia-forming cycle (R) has one episode of deposition and four episodes of recrystallization and/or progressive deformation identified: [1] deposition of immature sediments, in a back-arc environment, close to the source rock (R0); [2 and 3] long-lasting high-temperature, high-pressure metamorphic condition, related with a fold-and-thrust belt (R1-R2). [4] metamorphic climax up-to granulite facies metamorphism (R3). [4] end of the collisional event, characterized by post-deformational granitoids (R4). We interpret that R1-R2 coincides with the older syn-deformational granitoid age of 1068 ± 28 Ma. A tectonic exhumation in R3 is related to syn- to tardi-granitoids at 1032 ± 12 Ma. It was followed by an R4 event of crustal delamination at 1006 ± 13 Ma. The reset in Rb-Sr and K-Ar systems were due to posterior metamorphic cycle, in the greenschist facies. We interpret that as caused by far-field thermal anomalies of Neoproterozoic-Paleozoic orogenic events, such as Panantartican-Pananfrican-Gondwanides. The anchimetamorphic cycle, below 300°C , is related to still uncomprehended Jurassic-Cretaceous events of rifting in the region. MEBC constituted the deformational front of Natal-Maud orogeny by the end of Mesoproterozoic, standing right on the middle of Margate and Heimefrontfjella terranes. We suggest that the collision of Kaapvaal and Coats-Patagônia cratons generated not only Dronning Maud Land Mesoproterozoic rocks, but also MEBC, Natal Province, Cape Meredith Complex, and rocks that generates Beattie-A anomaly. Coats-Patagônia consisted of a Laurentian appendix. Thus, MEBC and Natal-Maud should also be addressed as Grenvillian.

1 1 INTRODUÇÃO

2 Rodínia é uma palavra russa polissêmica. De maneira geral, significa *to beget*
3 ou ainda *to grow* (Li et al., 2008; McMenemy e McMenemy, 1990). Isto é,
4 representa não apenas crescimento, mas também o desenvolvimento natural da
5 maturidade. Seu sentido foi incorporado à geologia, representando uma
6 configuração hipotética de massas continentais com ápice entre a transição Meso-
7 Neoproterozóico. Durante este período, diversos blocos se amalgamaram para
8 formar um supercontinente através de um processo chamado “orogêneses
9 formadoras do Rodínia” (a.k.a. *Rodínia-forming orogens*; Li et al., 2008; Roberts et
10 al., 2015). No entanto, diversas “crias” continentais de menor escala ainda são
11 consideradas “bastardas”. Isto é, unidades geológicas que ainda não são
12 consideradas em reconstruções paleotectônicas, devido à pouca representatividade
13 em área ou ainda desconhecimento geral acerca da área (Fuck et al., 2008; Li et al.,
14 2008).

15 Nesse contexto emerge o embasamento ígneo-metamórfico recuperado ao
16 oeste do Platô de Falkland, mais precisamente no Banco de Maurice Ewing (*Maurice*
17 *Ewing Bank*), durante a campanha de perfuração do *Deep-Sea Drilling Project*
18 (DSDP) 330, foco deste estudo. Os dados geológicos, geoquímicos e
19 geocronológicos e interpretações iniciais foram apresentados em Barker et al.
20 (1977a, 1977b) e Beckinsale et al. (1977). Mais recentemente, Chemale Jr. et al.
21 (2018) realizam estudos geocronológicos com maior precisão e exatidão, que
22 serviram de base para o presente estudo. As rochas recuperadas foram inicialmente
23 datadas por método Rb-Sr e K-Ar em rocha total como representativas do período
24 Ediacarano-Fortuniano por Beckinsale et al. (1977). No entanto, Chemale Jr. et al.
25 (2018), com aplicação do método U-Pb e Lu-Hf em zircão, reinterpreteram-nas como
26 metamorfizadas e, quando aplicado, geradas por um evento regional de idade
27 Esteniano com contribuição de crosta juvenil e retrabalhada. Este fato levou a
28 reinterpretação tectônica da região, relacionando as rochas do embasamento de
29 Maurice Ewing Bank com as rochas de Cape Meredith Complex (Ilhas Falkland;
30 Chemale Jr. et al., 2018). Os aspectos petrográficos, no entanto, foram estudados
31 unicamente por Tarney (1977), que identificou um evento metamórfico de alto grau.
32 Desde os estudos pioneiros de Tarney, as rochas de MEBC não foram revisitadas.

33 **1.1 Objetivos**

34 Este trabalho visa estudar, definir e interpretar as rochas Mesoproterozóicas
35 advindas do embasamento de Maurice Ewing Bank (Maurice Ewing Bank Complex –
36 MEBC; Chemale Jr. et al., 2018), usando petrografia e geoquímica. Para que, deste
37 modo, defina-se o ambiente da formação das rochas, bem como a trajetória de
38 recristalização/deformação ao longo do tempo (PTt) para que se possa estabelecer
39 com maior precisão os processos tectono-metamórficos envolvidos na geração do
40 MEBC e, ao mesmo tempo, comparar com terrenos adjacentes da orogenia Natal-
41 Maud (1.2-1.0 Ga).

42

43 2 GEOLOGIA REGIONAL

44 O Planalto das Malvinas é uma projeção submarina da margem continental da
45 América do Sul que se estende por aproximadamente 1800 km a leste das Ilhas
46 Malvinas. Ao norte, é limitado por uma escarpa transformante com tendência W-E,
47 chamada de Zona de Falha de Malvinas/Agulhas (*Malvinas-Agulhas Fracture Zone -*
48 *MAF*), que acomoda uma feição de 1400 km de extensão que limita a interface
49 continente-oceano da Plataforma Argentina (Kimbell e Richards, 2008). Ao Sul, por
50 outro lado, é diretamente limitado pelo *North Scotia Ridge (NSR)*. Possui suave
51 mergulho em direção leste. No entanto, em seu extremo leste, há uma estrutura
52 morfológica chamada Maurice Ewing Bank (MEB; Barker, Dalziel e Wise, 1974;
53 Ludwig, Krasheninnikov *et al.*, 1983). O sítio 330, realizado nas coordenadas
54 50°55.19'S, 46°53.00'W, localiza-se a oeste desse alto morfoestrutural e consiste de
55 dois cores, 16 e 17 (Figura 1).

56

57 Figura 1 – A) Localização geográfica do Maurice Ewing Bank e terrenos com
 58 assinaturas isotópicas e/ou idades que remontam o Mesoproterozoico, utilizando a
 59 Projeção Antártica Cônica de Lambert; B) Localização do site 330 que engloba os
 60 cores 16-17. Legenda das abreviações: DM - Deseado Massif, SCM: Somun Cura
 61 Massif, CMC – Cape Meredith Complex, MEB - Maurice Ewing Bank, NqB -
 62 Namaqua Belt, NtB – Natal Belt. Estruturas: MAFZ – Malvinas-Agulha Fault Zone,
 63 NSR – North Scotia Ridge.

64

65 Após ultrapassar uma lâmina d'água de 2626 m, foram perfuradas, então, 550
 66 m de rochas sedimentares que representaram, em sua maioria, um registro
 67 deposicional de idade sin- a pós-Jurássica. Após perfuração e testemunhagem do
 68 material sedimentar, 19,5 m de embasamento gnáissico-granítico foram atingidos,
 69 claramente representando a ínfima parcela de um complexo ígneo-metamórfico
 continental de idade Pré-Cambriana, afetado por eventos termais em diversos

70 momentos durante o Eratema Paleozóico (Barker et al., 1977a). O material utilizado
71 neste estudo derivará desta parcela do embasamento.

72 2.1 Bloco Falkland (Malvinas)

73 A única exposição Mesoproterozóica das Ilhas Malvinas consiste de delgada
74 seção aflorante, encontrada na porção sul da *West Falkland (Malvinas) Islands*
75 (Figura 2), chamada de Cape Meredith Complex. Thomas et al. (1997) mapearam e
76 classificaram as rochas em duas unidades litoestratigráficas distintas.
77 Subsequentemente, Jacobs et al. (1999) as dataram. As unidades, conforme
78 Thomas et al. (1997), são: i) Big Cape Fm., principalmente composta de anfibolitos
79 com idades ^{40}Ar - ^{39}Ar Bt variando de 1009 ± 14 até 1015 ± 6 Ma intercalados com
80 gnaisses félsicos de idade 1118 ± 8 Ma. Esta unidade representa uma sequência
81 Vulcano-sedimentar que evoluiu durante a transição do Meso-Neoproterozóico
82 (Jacobs et al., 1999); ii) Suite de Granitóides relacionada com três eventos de
83 granitogênese distintos. O primeiro, nomeado G1, é principalmente composto por Bt-
84 Granodioritos localmente deformados que sugerem gênese sin-deformacional, com
85 idades em torno de 1090 Ma (U-Pb em zircão). O G2, composto *sensu lato* por
86 augen-ortognaisses, possui uma idade de 1135 ± 11 Ma U-Pb nos núcleos de zircão,
87 enquanto as bordas possuem idades de 1003 ± 14 Ma. O leucogranito G3 intrude as
88 unidades mais velhas e possui uma idade de cristalização (U-Pb em zircão) que
89 coincide com o evento metamórfico de G2 (1003 ± 14 Ma) (Jacobs et al., 1999).
90 Portanto, o evento metamórfico de G2 e a granitogênese de G3 são resultados de
91 um evento anatético regional (Jacobs et al., 1999; Thomas et al., 2000). ^{40}Ar - ^{39}Ar em
92 muscovita e biotita com idades de 989 ± 3 Ma e 989 ± 7 Ma para G2 e G3,
93 respectivamente, sugerindo que Cape Meredith Complex provavelmente foi
94 submetido a um resfriamento abaixo dos $\sim 300^\circ\text{C}$ em apenas alguns milhões de anos
95 (Jacobs et al., 1999). Não há evidências direta de metamorfismo relacionado com
96 orogenias pós Mesoproterozóicas (Thomas et al., 2000, 1997). Diversos diques
97 lamprófíricos cortam o complexo, com idades que variam do Paleozóico ao
98 Mesozóico (Cingolani e Varela, 1976; Thistlewood et al., 1997; Thomas et al., 2000,
99 1998).

100

101

102

103

Figura 2 – Mapa geológico do procurador aflorante do bloco Falkland (Malvinas), Cape Meredith Complex. Retirado de Thomas et al. (1997).

104 2.2 Bloco Agulhas

105 O Platô de Agulhas Plateau é um alto oceânico situado 500 km SE do Cabo
106 da Boa Esperança, onde, em seu máximo, possui 700 km de comprimento e 400 km
107 de largura (Parsiegla et al., 2008; Figura 3). Atualmente, Barrett (1977), Parsiegla et
108 al. (2008) e Scrutton (1973) sugerem, através de modelagem geofísica reversa, que
109 a porção norte do bloco tem uma composição de crosta oceânica, com idades
110 variando de 80 a 100 Ma (Gohl e Uenzelmann-Neben, 2001; Uenzelmann-Neben et
111 al., 1999). Na parte sul, Parsiegla et al. (2008) identificaram um padrão de crosta fina
112 que pode conter fragmento de crosta continental, sugerindo deste modo um
113 ambiente de crosta superextendida. As únicas rochas de embasamento
114 testemunhadas na região foram descritas por Allen e Tucholke (1981), estando
115 inseridas, na sua maioria, em um contexto de metamorfismo regional, indo de fácies
116 xisto verde até eclogito. Eles dataram dois gnaisses, pelo sistema K-Ar em biotita,
117 obtendo idades de 1074 ± 36 Ma e 1105 ± 36 Ma, respectivamente. Essas idades
118 são relacionadas com o metamorfismo causado pelas orogenias formadoras do
119 Rodínia (Roberts et al., 2015). No entanto, duas amostras resultaram em idades de
120 478 ± 17 e 498 ± 17 Ma, provavelmente resultado de um *reset* termal relacionado
121 com as orogenias Panafricanas-PanAntárticas que marcaram o final do
122 Neoproterozóico. É importante enfatizar que os autores se opõem a ideia que as
123 rochas foram transportadas por processos glaciectônicos. Chemale Jr (pers.
124 commut.) datou-as, através do método U-Pb em zircão, obtendo resultado que
125 variam de 1.2 a 1 Ga, portanto, comprovando a similaridade das rochas com os
126 eventos de amalgamação do Rodínia.

127

128

129

130

Figura 3 – Localização do Platô de Agulhas. As dragagens de número 25, 26, 27 e 28 possuem amostragem do embasamento Mesoproterozóico. Retirado de Allen e Tuscholke (1981).

131 2.3 Província Natal

132 A Província Ígneo-Metamórfica Natal localiza-se ao leste da África do Sul e
133 consiste de três terrenos acrescidos, produtos de diversos nappes com trend NE
134 Figura 4. São eles: Tugela, Mzumbe e Margate (Cornell et al., 2006). Esses terrenos
135 foram acrescidos na margem SE do cráton de Kaapval no final do
136 Mesoproterozóico, sendo submetidos a metamorfismo na fácies anfibolito superior
137 até granulito inferior. Posteriormente, foram submetidos a metamorfismo regressivo
138 para a fácies xisto verde (Arima e Johnston, 2001; Cornell et al., 2006; Johnston et
139 al., 2001). Os terrenos Tugela e Mzumbe registram um magmatismo de arco de ilhas
140 entre 1200 Ma e 1160 Ma, seguido pela acreção na margem sul do cráton Kaapval,
141 por volta de 1150 Ma (Arima e Johnston, 2001; Mendonidis et al., 2015). O terreno
142 Margate é relacionado com magmatismo de arco continental até aproximadamente
143 1120 Ma. Em sucessão, ocorre um vulcanismo bimodal, resultado de eventos
144 extensionais, antecedendo a acreção do terreno na porção sul de Mzumbe, por
145 volta de 1090 Ma. Próximo à zona de sutura, devido a esta configuração colisional,
146 ocorre um metamorfismo de alta temperatura e baixa pressão, com evento de
147 anatexia regional, que levou a criação de grandes volumes de granitos derivados da
148 fusão no limite arco-crosta (Cornell et al., 2006; Mendonidis et al., 2015; Mendonidis
149 e Grantham, 2003; Spencer et al., 2015). Spencer et al. (2015) identificaram que
150 após a acreção e amalgamação do terreno, por volta de 1085 Ma, ocorreu um
151 colapso extensional, caracterizado pela intrusão de corpos máficos e suítes alcalinas
152 intermediárias, produto de tanto *underplating* quanto delaminação da crosta.
153 Isótopos de Nd e Hf sugerem que as rochas magmáticas do Cinturão Natal
154 derivaram de crosta continental juvenil, inicialmente gerada por um magmatismo de
155 arco de ilhas e, subsequentemente, retrabalhada por eventos acrescionários
156 (Mendonidis et al., 2015a).

Figura 4 Superior - Localização da Província Natal em relação ao continente Africano. Inferior (a) – Divisão dos três terrenos: Tugela ao norte, Mzombe no centro e Margate ao sul; (b) Detalhamento da porção sul da província. Retirada de Spencer et al. (2015)

157 2.4 Dronning Maud Land – Terras da Rainha Maud

158 Constituindo 1/6 da área total do continente Antártico, Dronning Maud Land é
 159 uma superprovíncia geológica formada por rochas predominantemente geradas durante
 160 o Mesoproterozóico-Neoproterozóico, de gênese complexa remontando a acreção e
 161 posterior separação de diversos terrenos, simbolizando orogêneses e tafrogêneses
 162 de nível intracontinental, ímpares na evolução de supercontinentes como Rodínia,
 163 Gondwana e Pangea (Bisnath et al., 2006; Harris, 1999; Harris et al., 1995; Jacobs
 164 et al., 2015; Figura 5).

165 As Terras da Rainha Maud consistem, simplificada-mente, de um núcleo
166 Paleoproterozóico, Grunehogna Craton, na qual acredita-se ser um bloco
167 pertencente ao Cráton Kalahari (Jacobs et al., 2008). Adicionalmente, são formadas,
168 de oeste a leste, pelos terrenos Heimefrontfjella (Arndt et al., 1991), Kirwanveggen
169 (Harris, 1999), Sverdrupfjella (Board et al., 2005), Gjelsviksfjella (Bisnath et al.,
170 2006), Mühlig-Hofmannfjella (Owada et al., 2003), Central Dronning Maud Land
171 (Jacobs et al., 2003b) e Sør Rondane (Masao et al., 1996). Genericamente, estes
172 terrenos, com exceção dos dois últimos, representam principalmente a
173 amalgamação, na transição Meso-Neoproterozóico, de um bloco continental
174 desconhecido ao cráton de Kalahari, com metamorfismo regional de alta pressão
175 associado à criação de expressivos volumes de magma (Jacobs et al., 2008). Os
176 blocos Central Dronning Maud Land e Sør Rondane possuem rochas de assinatura
177 isotópica juvenil, além de idades U-Pb mais jovens que os terrenos adjacentes
178 (Jacobs et al., 2003a, 2003b, 2015). Jacobs et al (2015) atribuem estas rochas como
179 pertencentes a um arco de ilhas, de idade Steniana.

180 A grande maioria destes blocos foram submetidos, no final do
181 Neoproterozóico pelos processos decorrentes da orogenia Ross (Bisnath et al.,
182 2006), tais como *overprint* metamórfico e geração de expressivos volumes de
183 magma alcalino. Ainda, relacionado à abertura do Wedell Sea, já no Mesozóico, há a
184 presença de diversos diques máficos de idade predominantemente Jurássica (Bauer et
185 al., 2003a; Harris et al., 1991). Através do estudo de traços de fissão em apatita,
186 titanita e zircão, além de isótopos do sistema U-Pb-He foi observado que as rochas
187 passaram por um rápido soerguimento na transição Mesozóico-Cenozóico,
188 interpretado como causado pela flexura isostática causada pela massa das geleiras
189 do continente Antártico (Emmel et al., 2009, 2008).

190

191 Figura 5 – Mapa de localização do *Dronning Maud Land* em relação à Antártica.
 192 Notar a relação de proximidade com o cráton de Grunehogna. Retirado de Board et
 193 al. (2005).

194 2.5 Coats Land

195 O bloco de *Coats Land* é uma entidade geológica distinta no domínio do Leste
 196 da Antártica (Loewy et al., 2011; Figura 6). Apenas dois afloramentos são
 197 acessíveis, compostos de riolitos e granófiros não deformados com idade de $1112 \pm$
 198 4 Ma (Gose et al., 1997). No entanto, sua expressão areal estende-se em
 199 subsuperfície até os limites do Dronning Maud Land Central. Jacobs et al. (2015,
 200 2008) consideram que os eventos geológicos ocorridos no Dronning Maud Land são
 201 resultado da colisão entre *Coats Land* e cráton de Grunehogna. Loewy et al. (2011)
 202 identificaram que as rochas de Coats Land possuem similaridade isotópica com
 203 rochas da orogenia Grenviliana, no Laurentia. Ainda, os autores supracitados
 204 coletaram dados de paleomagnetismo, demonstrando que, de fato, os terrenos
 205 Grenville e Coats eram adjacentes. Da mesma forma, relacionam o terreno com

206 duas unidades específicas: (i) embaimento de Ouachita, no Texas-Novo México e
 207 (ii) Terreno Cuyania, na Argentina.

Figura 6 – Superior – Localização do terreno *Coats Land* em relação à Antártica. Inferior – Área aflorante do terreno de Coats, representando dois Nunataks da região: *Littlewood* e *Bertrab*. Retirada de Gose et al. (1997).

208

209 2.6 Shackleton Range

210 *Shackleton Range* é uma província na Antártica Leste (Figura 7) composta
 211 por três terrenos distintos: i) o terreno sul possui zircões detriticos com idades em

212 torno de 2850 Ma, magmatismo entre 1850-1810 Ma, sendo submetidas a eventos
 213 de metamorfismo de médio a alto grau em torno de 1700-1680 Ma, com reativação
 214 no Paleozóico, em 510 Ma; ii) terreno leste formado por granitóides com ca. 1060
 215 Ma, com metamorfismo associado em torno de 600 Ma; iii) terreno norte,
 216 caracterizado por diorites e granitos com idade de 530 Ma, intrudidos sob
 217 paragneisses e rochas máfica-ultramáficas, onde, na passagem Neoproterozóico-
 218 Paleoproterozóico, foram submetidos a eventos metamórficos de médio a alto grau,
 219 com clímax em fácies eclogito (Will et al., 2010, 2009).

220

221 Figura 7 – Mapa geológico simplificado de *Shackleton Range*. Retirado de Will et al.
 222 (2009).

223 2.7 West Antarctica

224 As únicas rochas conhecidas de idade Proterozóica do oeste da Antártica são
 225 gnaisses granodioríticos intrudidos por diques máficos e camadas de microgranitos
 226 na região conhecida como *Haag Nunataks*. Isócronas de Rb-Sr em rocha inteira
 227 tiveram idades de 1176 ± 76 Ma para os gnaisses granodioríticos e 1058 ± 53 Ma
 228 para os microgranitos, respectivamente (Millar e Pankhurst, 1987). Conforme
 229 apontado por Millar e Pankhurst (1987), essas rochas permaneceram tectônica- e

230 termicamente impertubáveis durante o tempo. As assinaturas de $^{87}\text{Sr}/^{86}\text{Sr}$ e ϵNd são
231 típicas de crosta derivada de orogenias formadoras do Rodínia, demonstrando
232 similaridades com unidades de, por exemplo, Cape Meredith Complex (Thomas et
233 al., 2000).

234 Os granitóides do Jurássico que intrudem as rochas sedimentares do bloco
235 Ellsworth-Whitmore possuem idades de T_{DM} entre 1370-1600 Ma. Esses valores são
236 coerentes com os valores de T_{DM} encontrados nos granitóides Paleozóicos e
237 Mesozóicos da Patagônia (Pankhurst et al., 2006).

238 Na Península Antártica há evidências estratigráficas que, abaixo das rochas
239 predominantemente Paleozóicas e Mesozóicas, há um embasamento Proterozóico.
240 As idades mais antigas atestadas nessa região são gnaisses de aproximadamente
241 640 Ma, 410 ± 15 Ma e 426 ± 12 Ma (Rb-Sr em rocha total). No entanto, elas
242 possuem idades de T_{DM} entre 900-1200 Ma (Wareham et al., 1998). Também, em
243 outras localidades da Península Antártica há granodioritos e ortognaisses
244 granodioríticos Triássicos com T_{DM} de 1100-1750 Ma.

245 **2.8 Província Geológica Patagônia**

246 De acordo com Ramos (2008) e Ramos et al. (2004), o embasamento da
247 Patagônia é dividido em dois domínios tectônicos (Figura 8): (i) Maciço de Somun
248 Cura (a.k.a. *Northern Patagonia Domain, basement*, etc) e (ii) Maciço de Deseado,
249 localizado ao sul. De maneira geral, a Patagônia é delimitada ao norte com o terreno
250 Chileno e cinturão de dobramento Sierra de La Ventana. Ao Sul, é delimitada por
251 bacias sedimentares Meso-Cenozóicas e rochas relacionadas à orogenia Andina. O
252 maciço de Somun Cura é composto por rochas ígneo-metamórficas com um *trend*
253 NW-WNW e idades que variam do Ordoviciano ao Permiano. O metamorfismo,
254 quando presente, é até a fácies anfíbolito (Basei et al., 1999; Llambías et al., 2002;
255 Ramos, 2008; Varela et al., 1999; von Gosen, 2003). A Bacia de Colorado a separa
256 do Maciço de Deseado. Gericamente, é composto de rochas ígneas que variam
257 entre 420 e 380 Ma (Basei et al., 2005). O metamorfismo, quando presente, ocorreu
258 por volta de 360 Ma (U-Pb em zircão) e 375-310 Ma (K-Ar em titanita; Pankhurst et
259 al., 2006). As rochas geradas neste domínio são derivadas do processo tectono-
260 termal que afetou um hipotético arco magmático durante o Eo-Paleozóico
261 (Pankhurst et al., 2006; Ramos, 2008).

262 Mesmo que a cristalização e idade de metamorfismo de ambos blocos de fato
263 indicam variações de gênese e metamorfismo ao longo do Paleozóico, a unidade
264 apresenta idades modelo T_{DM} entre 1.7 e 854 Ma. Este dado sugere que as rochas
265 da Patagônia derivaram de uma crosta juvenil Mesoproterozoica, relacionada com
266 os eventos de formação do Rodínia (Pankhurst et al., 2006; Roberts et al., 2015;
267 Wareham et al., 1998). Além disso, métodos como $^{87}\text{Sr}/^{86}\text{Sr}$ e ϵNd também
268 demonstram mesma derivação Mesoproterozóica (Pankhurst et al., 2006). Diversos
269 trabalhos recentes fomentam este dado (e.g. Martínez Dopico et al. 2011; Mundl et
270 al., 2015), correlacionando xenólitos mantélicos encontrados tanto no terreno norte,
271 quanto no sul, com a crosta gerada no Rodínia e, ainda mais antiga, provavelmente
272 relacionada com a orogenia Grenviliana (Mundl et al., 2015). Martínez Dopico et al.
273 (2011) correlacionaram o maciço Somun-Cura com o terreno Cuyania, até então
274 considerado alóctone à evolução sul-Americana, e relacionável, mais uma vez, com
275 a orogênia Grenviliana, no Laurentia.

276

277 Figura 8 – Mapa simplificado dos maciços da Patagônia e terrenos sobrejacentes
 278 como Chilenia, Cuyania, Pampia e Río de la Plata. Retirado de Schilling et al. (2008)

279 2.9 Terreno Cuyania

280 O embasamento do terreno Cuyania é constituído de rochas com idade dos
 281 eventos formadores do Rodínia (Kay et al., 1996). Thomas e Astini (1996) sugerem
 282 que o embasamento é similar ao Sistema Grenvilliano do Laurentia (Figura 8). A
 283 idade U-Pb em zircão varia de ca. 1200 a 1000 Ma em diferentes setores do terreno
 284 (Casquet et al., 2001; Kay et al., 1996; Sato et al., 2004; Thomas e Astini, 1996). A
 285 presença de fauna típica do Laurentia e dado paleomagnético confirmam o caráter
 286 alóctone do terreno (Benedetto, 2004; Rapalini e Astini, 1998). Ramos (2010) afirma
 287 que a ausência de eventos magmato-metamórficos Pampeano ou Brasileiro indica
 288 que o terreno não fez parte da amalgamação Neoproterozóica do Gondwana.

289 2.10 Terreno Chilenia

290 Conforme Ramos et al. (1986), este terreno foi definido sendo limitadamente
291 aflorante seguindo a tendência de alinhamento axial da cordilheira (Figura 8; Figura
292 9). Ramos e Basei (1997) dataram rochas metamórficas de alto grau, adjacentes a
293 uma zona ofiolítica, de idade desconhecida, que separa este terreno de seu vizinho
294 a leste, Cuyania. Idades entre 1060 e 1080 Ma foram adquiridas na zona de Codon
295 del Portillo, através de U-Pb em zircão, que são coincidentes com o metamorfismo
296 existente, por exemplo no Western Dronning Maud Land (Arndt et al., 1991; Jacobs
297 et al., 2003c), Província Natal (Mendonidis e Armstrong, 2016; Spencer et al., 2015b)
298 e Falkland-Malvinas-Maurice Terrane (F2MT; Chemale Jr. et al., 2018; Jacobs et al.,
299 1999).

305 3 RODÍNIA: ORIGEM, NOME E EVOLUÇÃO

306 Rodínia é uma palavra derivado do russo “*rodit*”, usada de modo a
307 homenagear o papel da pesquisa soviética no Pré-Cambriano (McMenamin e
308 McMenamin, 1990, p. 95). Sua polissemia, em inglês, é incorporada a três verbos:
309 “*to beget*”, “*to grow*” ou ainda “*to give birth*” “*To beget*” é um verbo de difícil tradução,
310 significa gerar algo, normalmente uma criança, referindo-se especificamente ao
311 papel dos pais. No entanto, não parece completa sem “*to give birth*”, dar à luz e “*to*
312 *grow*”, o desenvolver natural da maturidade. Portanto, é ampla: Rodínia gerou os
313 supercontinentes, dando à luz aos primeiros animais. Suas margens serviram como
314 berço, um ambiente propício para a evolução da vida (McMenamin and McMenamin,
315 1990). No entanto, sua origem geológica é pretérita, advindo de Valentine e Moores
316 (1970), que teorizaram um supercontinente, chamado Pangea I. De idade Pré-
317 Cambriana, este supercontinente englobava todos os continentes da Terra, detendo
318 os principais fatores para a diversificação das formas de vida.

319 Hoje uma verdade geológica em pleno desenvolvimento, o supercontinente
320 Rodínia possui diversas teorias de evolução ao longo do tempo geológico. No
321 entanto, a maior parte das reconstruções partem do pressuposto do Laurentia como
322 centro do mundo. Os principais modelos em voga são SWEAT (Dalziel, 1991;
323 Hoffman, 1991; Moores, 1991), Missing Link (Li et al., 1995), AUSWUX (Brookfield,
324 1993), SAMBA (Johansson, 2014, 2009) e WALahari (Pisarevsky et al., 2003; Powell
325 et al., 2001). Todos os modelos possuem, em algum ponto, potencialidades e pontos
326 fracos, haja visto nenhuma solução ser única (Li et al., 2008, Figura 10a).

327 3.1 Modelos da evolução do Rodínia

328 3.1.1 SWEAT – *SouthWest United-States East Antarctica*

329 A correlação estratigráfica, metalogenética e paleomagnética de rochas Pré-
330 cambrianas do oeste do Canadá e sul da Austrália levou Bell e Jefferson (1987) a
331 proporem que estes dois blocos estavam originalmente conectados e, a partir de 1.2
332 Ga começaram um processo de rifteamento e desenvolvimento de margem passiva.
333 Inspirado nessas similaridades, Dalziel (1991), Hoffman (1991) e Moores (1991),
334 propuseram o modelo *Southwestern United States-East Antarctica* (SWEAT),

335 sugerindo que as rochas, até então de origem controversa, de terrenos encontrados
336 em *Nimrod Glacier*, *Pensacola Mountains* e *Maud Belt*, com idades entre $\approx 1.2-0.8$
337 Ga, formavam uma extensão das província Grenviliana, região leste da América do
338 Norte. Ênfase também foi dada para idades similares das rochas do *Shackleton*
339 *Range* e o terreno adjacente de *Coats Land* aquelas características da Província
340 Yavapai-Mazatzal (Figura 10). Moores (1991) sugeriu que os crátons do norte e
341 oeste australianos provavelmente não faziam parte da extensão SWEAT até a
342 colisão do final do Mesoproterozóico, caracterizado pelo cinturão Albany-Fraser-
343 Musgrave.
344

345

346 Figura 10 – Modelo SWEAT proposto por Hoffman (1991). A – Reconstrução dos
 347 grandes blocos continentais amalgamados, formando o primeiro mapa oficial do
 348 supercontinente Rodínia, com a posição dos continentes há aproximadamente 700
 349 Ma. B – Idealização do *break-up* entre a margem Proto-andina e Laurentia ocorrido,
 350 conforme o autor, há aproximadamente 500 Ma.

351

352 Em uma visão minuciosa das províncias cristalinas e proveniência das bacias,
 353 Borg e DePaolo (1994), através da análise detalhada de dados isotópicos,
 354 cronológicos e geoquímicos, identificaram descontinuidades na conexão SWEAT.
 355 Como resultado, de modo a manter o modelo SWEAT viável, os autores sugeriram
 356 que os terrenos Mesoproterozóicos das Montanhas Transartáticas mais jovens que
 ca. 1000 Ma eram provavelmente alóctones, sendo acrescentados às margens do

357 Laurentia após a abertura do oceano proto-Pacífico. No entanto, conforme apontado
358 por Li et al. (2008), não há evidência geológica para o *docking* destes terrenos,
359 carecendo de deposição advinda de um período mais antigo que 668 ± 1 Ma
360 (Goodge et al., 2002).

361 Li et al. (2008) apontaram outras evidências que não fomentam o modelo
362 SWEAT, como: (i) falta de continuação da província magmática transcontinental do
363 sul do Laurentia (1500-1350 Ma; até as *Transantarctic Mountains*; (ii) discrepâncias
364 no evento de pluma mantélica do Neoproterozóico entre a conexão SWEAT (Li et al.,
365 1999; Park et al., 1995; Wingate et al., 1998); (iii) bacias do oeste da América do
366 Norte (e.g. *Belt Basin*) possuem áreas fonte com idades de 1786-1642 Ma, 1600-
367 1590 Ma e 1244-1070 Ma, não identificadas no Leste da Antártica (Ross et al., 1992;
368 Ross and Villeneuve, 2003); (iv) a conexão SWEAT, inicialmente proposta por
369 Dalziel (1991) e Moores (1991), provou-se inatingível tanto paleomagneticamente
370 (Gose et al., 1997), quanto geologicamente (Jacobs et al. 2003a; 2003b). No
371 entanto, cabe ressaltar que, conforme Li et al. (2008), o Laurentia se conectou com o
372 Kalahari em ca. 1090-1060 Ma, permanecendo deste modo até o *break-up* do
373 Gondwanaland (Jacobs et al., 2003b, 2003a; J. Jacobs et al., 2008). Li et al. (2008)
374 enfatizaram que se de fato houve cinturões orogênicos conectando Laurentia,
375 Austrália e *East Antarctica*, ou se conexão SWEAT existiu, ela deve ser Grenviliana
376 ou posterior. Há a possibilidade da comprovação do modelo SWEAT, através de
377 dados paleomagnéticos, após ca. 1050 Ma (Powell et al., 1993). No entanto, essa
378 conexão não é possível em ca. 1200 Ma (Pisarevsky et al., 2003). Portanto, Li et al.
379 (2008) não aceitam uma conexão SWEAT em momentos tardi-Paleoproterozóico,
380 isto é, ca. 1800-1600 Ma.

381 3.1.2 *Missing link*

382 Proposto inicialmente por Li et al. (1995), o modelo Missing Link coloca o
383 *South China Block* entre os blocos Australia-Leste da Antártica (Li et al., 2008;
384 Figura 11). O modelo foi concebido de modo a (i) preencher o vazio entre as
385 províncias crustais da Austrália - *East Antarctica* e o Laurentia; (ii) devido às
386 similaridades estratigráficas observadas por Eisbacher (1985) entre o sul da China,
387 Austrália e oeste do Laurentia; (iii) similaridades entre províncias crustais do bloco
388 Cathaysia e sul do Laurentia e (iv) a necessidade de uma área fonte para as Bacias

389 cronocorrelatas do oeste norte-americano, com picos de idade de proveniência
 390 similares àquelas encontradas no terreno de Cathaysia (Ling et al., 2003; Ross e
 391 Villeneuve, 2003).

392 Por exemplo, há diversas similaridades entre os depósitos de rift encontrados
 393 na parte sul da China e o leste da Austrália. No entanto, dos 4 episódios de
 394 magmatismo-*rifting*, apenas os 2 mais jovens são documentados na Laurentia (ver Li
 395 et al., 2008). Ainda, é interpretado que a colisão entre a Laurentia-Cathaysia e bloco
 396 Yangtzie é limitada a, no máximo, 1140 Ma e durou até o circa de 900 Ma
 397 (Greentree et al., 2006; Li et al., 2003; Ling et al., 2003).

398

399 Figura 11 – O modelo Missing-link conforme concebido por Li et al (1995) e
 400 aprimorado por Li et al (2008).

401 De maneira geral, outra vantagem do modelo é que não necessita de um
 402 *apparent polar wander path* (APWP) entre os continentes relevantes entre 1 Ga e
 403 900 Ma. Com os dados paleomagnéticos disponíveis atualmente é possível uma

404 conexão entre os blocos da Austrália-sul da China-Laurentia durante 820-800 Ma; no
 405 entanto, a partir de 750 Ma, eles devem ser separados (Li et al., 2008).

406 3.1.3 AUSWUX – Australia-Southwest US

407 Inicialmente proposta por Brookfield (1993), o modelo Australia-Southwest US
 408 (AUSWUX) foi concebido na equivalência de fraturas lineares supostamente
 409 formadas durante o break-up do Rodínia nas margens leste do cráton da Austrália e
 410 oeste do Laurentia (Figura 12). O modelo foi revisitado por Burrett e Berry (2000) e
 411 Karlstrom et al. (1999), principalmente por correlação e províncias cristalinas e
 412 estudo de proveniência entre os blocos.

413

414 Figura 12 – Modelo AUSWUX, conforme concebido por Brookfield (1993).

415

416 No entanto, Dieren e Crawford (2003) identificaram que os lineamentos que
 417 ocorrem na Austrália não são mais antigos que 600 Ma. Conforme Li et al. (2008),
 apesar de seus méritos, o modelo apresenta diversas dificuldades, tais como: (i)

418 dificuldades em explicar os dados esparsos de metamorfismo Greenwilliano no oeste
419 do Laurentia, norte de Queensland, Tasmania e orogenia Ross; (ii) ausência de
420 rochas graníticas e riolíticas com ca. 1400 Ma na Austrália, como são encontradas
421 no sul do Laurentia; (iii) o começo do rifte no Laurentia (ca. 750 Ma) é diferente do
422 observado no leste da Austrália (ca. 825 Ma); (iv) há uma incoerência nos dados de
423 paleomagnetismo de 1200 Ma com o modelo Pisarevsky et al. (2003). Em 1100-
424 1050 Ma, entretanto, os paleopólos são coerentes.

425 3.1.4 SAMBA – South AMerica-BAltica

426 Através da interpretação de compilações de dados geológicos gerais e
427 modelos de reconstrução de placas, foi proposto por Johansson (2014, 2009) um
428 modelo onde correlaciona-se, durante o Rodínia, o bloco Baltica com o Amazonia.
429 Esta correlação, conforme o já citado autor, ocorreu de 1.8 Ga até 0.8 Ga, onde, o
430 cráton West Africa servia como conexão entre o nordeste da Amazonia e sudeste de
431 Baltica. Deste modo, será considerado como SAMBA a amalgamação dos terrenos
432 Amazonia, Baltica e *West Africa* (Figura 13).

433 De maneira geral, em consonância com boa parte das reconstruções já
434 propostas, a parte noroeste do Baltica era conectada com o leste do Laurentia
435 (*Greenland*) de 1.9 Ga até 1.3 Ga. Johansson (2014) sugere uma configuração
436 como a proposta no modelo SWEAT (Moores, 1991). Deste modo, o cráton Kalahari
437 era anexado ao sudoeste do Laurentia e junto com o *East Antarctica*, juntamente
438 com o cráton do Congo, Tanzânia, São Francisco e Rio de la Plata.

439 Johansson (2009) sugere que para atingir o modelo padrão do Rodínia, o
440 bloco Baltica deve ter se separado do Laurentia e, junto com o bloco Amazonia e
441 *West Africa*, rotacionar aproximadamente 75°, em sentido horário, em relação ao
442 Laurentia. De modo a encaixar no modelo proposto do Gondwana, exige-se a
443 rotação de diversos crátons (e.g. Laurentia-Kalahari, *East Antarctica*) em ângulos
444 maiores que 90° no sentido anti-horário (Johansson, 2014). A separação do Rodínia
445 é interpretada como ocorrida por volta de 0.6 Ga, em resposta as rotações em
446 escala global. Da mesma forma, a abertura do oceano Proto-Pacífico e as colisões
447 Brasileiras/Panafricanas são relacionadas a este evento.

448

449 Figura 13 – Reconstrução do Rodínia (ca. 900 Ma) conforme modelo SAMBA
 450 (Johansson, 2014, 2009).

451 Fuck et al. (2008), ainda, sugeriram que as províncias Ventuari-Tapajós e Rio
 452 Negro-Juruena, chaves para a reconstrução do modelo, são truncadas ao norte por
 453 orogênias de idade Grenviliana. Este dado coloca em prova a estabilidade proposta
 454 pelo modelo do superbloco SAMBA durante 1.8 até 0.9 Ma (Pisarevsky et al., 2014).

455 Não são consideradas neste modelo as unidades formadoras do arco de Ilhas
 456 Steniano (TOAST; Jacobs et al., 2015 e Ruppel et al., 2018), localizadas tanto em
 457 terrenos como Central Dronning Maud Land e Sør Rondane (Jacobs et al., 2015;
 458 Ruppel et al., 2018) e Terreno Madagascan (Archibald et al., 2018).

459 3.1.5 WALahari – *Western Australia-KaLahari*

460 O modelo Western Australia-Kalahari (WALahari; Figura 14), inicialmente foi
 461 concebido por meio de dados paleomagnéticos de Pisarevsky et al. (2003), Powell et
 462 al. (2001) e Powell e Pisarevsky (2002). Subsequentemente, diversos dados
 463 geocronológicos deram suporte hipótese, como Fitzsimons (2002, 2003).

464 A concepção é de que o Kalahari estaria localizado junto ao oeste do *Western*
 465 *Australia block*, com o *Maud-Belt* adjacente à orogénia Pinjarra, de idade também

466 Grenviliana (Ksienzyk e Jacobs, 2015). A principal base teórica para a colisão entre
 467 o *Western Australia* e o Kalahari, no fim do Mesoproterozóico, foi a similaridade do
 468 espectro de idades e características estratigráficas observadas nos dois terrenos
 469 (Ksienzyk e Jacobs, 2015).

470

471 Figura 14 – Modelo WALahari, conforme concebido por Pisarevsky et al. (2003).
 472 Idealização do Rodínia há 900 Ma. Legenda: In – Índia; Ka – Kalahari, Au –
 473 Austrália; Ma – Mawson; T- Tarim; RP – Rio de La Plata; P – Pampean Terrane; SC
 474 – South China; La – Laurentia; Si – Sibéria; Am – Amazonia; WA – West Africa; B –
 475 Barentsia; Ba – Baltica; Ch – Chortis; Gr – Greenland; R – Rockall; O – Oaxaquia;
 476 Ba – Baltica.

477 Essencialmente, Fitzsimons (2002, 2003) comparou dados de proveniência e
 478 do *Maud Belt* de Arndt et al. (1991) e Harris (1999) e da orogenia Pinjarra do
 479 *Western Australia* de Bruguier et al. (1999) e Cobb et al. (2001). No entanto,
 480 Ksienzyk e Jacobs (2015b), com base em dados mais consistentes obtidos pelos
 481 autores, do leste da Antártica, e Ksienzyk et al. (2012), da orogenia Pinjarra,
 482 concluíram que a comparação direta dos metassedimentos das duas áreas
 483 demonstra uma incompatibilidade de área fonte, sugerindo diferentes sequências
 484 sedimentares.

485 Apesar disso, o espectro de idades dos grãos detríticos de zircão encontrados
486 no metassedimento não elimina a possibilidade do modelo WALahari ser aceitável
487 (Ksienzyk e Jacobs, 2015). De qualquer forma, os autores consideram a posição do
488 Kalahari adjacente ao SW Laurentia com o Namaqua-Natal-Maud Belt como a
489 contraparte colisional da orogenia Grenviliana.

490 3.1.6 TOAST – Tonian Oceanic Arc Super Terrane

491 Proposto inicialmente por Jacobs et al. (2015), o modelo TOAST (*Tonian*
492 *Oceanic Arc Super Terrane*) postula que as rochas de Central Dronning Maud Land
493 e Sør Rondane representam um amplo terreno de arco de ilhas, que, durante 1000-
494 900 Ga não faziam parte do supercontinente Rodínia (Figura 15). Conforme
495 apontado por Ruppel et al. (2018), a primeira evidência geológica do TOAST é
496 relacionada a uma fase principal de subducção que formou rochas magmáticas de
497 assinatura juvenil em torno de 995-975 Ma. É seguida por uma fase de gênese
498 similar, mas tenuemente mais jovem (960-925 Ma) nos terrenos localizados a SW do
499 Sør Rondane.

500 As unidades do TOAST, de maneira geral, possuem uma história de
501 polimetamorfismo com geração de grandes volumes de magma, datados em ca. 630
502 até 500 Ma. De maneira geral, as idades do *overprint* metamórfico diminuem de
503 oeste para o leste. Isto é interpretado por Jacobs et al (2015) como evidência que o
504 TOAST colidiu com o Kalahari primeiro, antes de colidir com o terreno Rukerland
505 e/ou Indo-Antártica em seu limite leste. Ainda, há um *overlap* de idades entre as
506 rochas TOAST e as localizadas à leste, compreendendo rochas do *Rayner Complex*.
507 No entanto, três principais diferenças emergem: i) longa história acrescional de
508 arcos de ilha formadores do *Rayner Belt* (entre 1400-900 Ma) que culminam em ii)
509 colisão continente-continente em ca. 950 Ma; iii) o TOAST possui uma pronunciada
510 assinatura juvenil, carecendo de qualquer indicativo de herança e *overprint*
511 metamórfico imediatamente após a formação da crosta (Figura 15).

512

513 Figura 15 – Reconstrução tectônica em (a) 1000 Ma e (b) 950. North America,
 514 vermelho (Ch, Chortis; G, Greenland; L, Laurentia); South America, azul marinho;
 515 (Am, Amazonia; Bo, Borborema; Pp, Paranapanema; RDLP, Rio de la Plata; SF, São
 516 Francisco) Baltica, verde; (Ba, Baltica); Siberia, grey; (Si, Siberia); India, continentes
 517 do Indian Ocean e Middle East (oriente médio), azul claro (A-A, Afif–Abas Terrane;
 518 Az, Azania; In, India); China, amarelo (Ca, Cathaysia, South China; NC, North
 519 China); Africa, laranja (By, Bayuda; C, Congo–Tanzania–Bangweulu Block; H,
 520 Hoggar; K, Kalahari; N-B, Nigeria–escarlata (NAC, North Australian Craton; SAC,
 521 South Australian Craton); Antarctica, roxo (Ma, Mawson; Ra, Rayner); Arcos Meso-
 522 Neoproterozoic, verde escuro; (DA, Dabolava Arc; SI, Southern Irumide; SR, Sør
 523 Rondane; TOAST, Tonian Oceanic Arc Super Terrane; UM, Unango–Marrupa; VC,
 524 Vijayan Complex; WC, Wanní Complex; KC, Kadugannawa Complex). Retirada de
 525 Archibald et al. (2018).

526

527 A sutura TOAST-Dronning Maud Land é considerada por Jacobs et al (2015)
 528 como o limite TOAST-orogênias Grenvilianas na Antártica. Os limites sul e leste são
 meramente especulativos.

529 4 ROTAÇÃO DAS ILHAS FALKLAND (MALVINAS) NO MESOZÓICO

530 As Ilhas Falkland (Malvinas), localizadas na plataforma Argentina, 500 km a
 531 leste da costa da Patagônia, possuem ativa participação na consolidação da Teoria
 532 da Deriva Continental e evolução do Gondwana. Conforme Ramos et al. (2017), três
 533 hipóteses sobre evolução tectônica das ilhas foram inicialmente propostas: (i) Du
 534 Toit (1937) colocou a ilha entre a América do Sul e África do Sul, (ii) Adie (1952), em
 535 contra partida, inverteu a posição atual das ilhas, colocando-as na borda leste da
 536 África do Sul, como um apêndice dos terrenos dobrados e um importante evento de
 537 rotação ocorrido no Mesozóico; (iii) Borello (1963) teorizou que as ilhas se
 538 mantiveram em uma posição similar, em relação a América do Sul, conforme a
 539 configuração atual (Figura 16).

540

541 Figura 16 – Posição das Ilhas Falkland (Malvinas) no contexto pre-break up
 542 conforme Du Toit (1937), Borello (1956) e Adie (1952). Retirada de Ramos et al.
 543 (2017).

544

545 Diversas aproximações avaliaram / fomentaram / desvalidaram essas
 546 hipóteses. Estas aproximações incluíram reconstruções paleogeográficas, análises
 paleomagnéticas, análise geocronológica dos diques Juro-Cretáceos (Mitchell et al.,

547 1986; Stone et al., 2009, 2008; Taylor and Shaw, 1989) e embasamento (Cingolani
548 and Varela, 1976; Jacobs et al., 1999; Thomas et al., 2000, 1997), proveniência das
549 sequências sedimentares (Ramos et al. 2017, dentre tantas outras). No entanto,
550 ainda não há consenso sobre a posição das ilhas durante sua evolução entre o
551 Mesoproterozóico e, principalmente, durante o Mesozóico. Assim sendo, serão
552 abordadas as principais características de cada hipótese, da mais antiga para a mais
553 recente.

554 3.4.1 Hipótese de Du Toit (1927)

555 As similaridades estratigráficas entre Sierra de La Ventana e Cape Fold Belt
556 levaram (Du Toit, 1927) a postular que as Ilhas Falkland (Malvinas) encontravam-se
557 na mesma latitude e no meio do caminho entre essas duas unidades. Conforme
558 pontuado por Ramos et al. (2017) esta hipótese foi principalmente baseada nos
559 estudos de Keidel (1916, 1913) e comprovada após a visita do pesquisador nos
560 depósitos da América do Sul. O principal argumento baseava-se na correlação dos
561 tilitos encontrados nessas três unidades, que além de mesma gênese deposicional,
562 possuíam mesma idade.

563 Existem dois problemas na hipótese de Du Toit. O primeiro, relacionado com
564 a vergência estrutural dos depósitos Paleozóicos das Ilhas Falkland (Malvinas), são
565 opostas as da Ventania e Cape Fold (S-N). É conhecido que a vergência dos tilitos
566 das ilhas tem sentido SW (Adie, 1952a; Baker, 1924). O segundo é relacionado com
567 a falta de correlação entre a Patagônia e as Ilhas Falkland (Malvinas). O motivo
568 principal baseia-se no fato de, no período em que o trabalho foi proposto, Du Toit
569 não tinha conhecimento dos depósitos glaciais Eo-Paleozóicos com idade de
570 deposição similar àqueles encontradas nos tilitos das Ilhas Falkland (Malvinas;
571 Griffis et al., 2014).

572 3.4.2 Hipótese de Adie (1952)

573 A hipótese correlaciona as Ilhas Falkland (Malvinas) com o oeste da África do
574 Sul. No entanto, baseia-se na rotação de 180° das ilhas para que haja uma maior
575 consistência na correlação. É estruturada nas seguintes premissas: (i) a rotação de
576 180° facilita a associação das unidades Mesoproterozóicas das ilhas com o terreno

577 Natal; (ii) com a rotação, torna-se aceitável a correlação das unidades estratigráficas
578 presente nas duas regiões; (iii) afinidades paleontológicas no mar Devoniano,
579 identificadas na fauna Malvinokafrica (Richter e Richter, 1942); (iv) a partir da
580 rotação as paleocorrentes das unidades glaciais do Eo-Paleozóico passam a ser
581 iguais; (v) os diques basálticos presentes nas ilhas podem ser correlacionados com
582 os diques doleríticos; (vi) estilo do padrão de dobras das ilhas se tornam similares ao
583 do *Cape Fold Belt*.

584 Diversos estudos paleomagnéticos feitos nos enxames doleríticos das ilhas
585 suportam a hipótese de Adie. Inicialmente, Mitchell et al. (1986) propuseram uma
586 paleolatidade similar ao Transkei, permitindo, desta forma, a localização das ilhas ao
587 leste da África do Sul. Um estudo mais consistente foi efetuado por Taylor e Shaw
588 (1989), com resultados aproximados. Uma rotação de 120° ocorreu durante o
589 Jurássico, seguida por uma rotação de 60° no Cretáceo durante a abertura do
590 Atlântico Sul (Stone et al., 2009; Storey et al., 1999). Ben-Avraham et al. (1993),
591 baseados nessas interpretações, propuseram a existência da Microplaca de Lafonia.
592 Para acomodar os tensores necessários para a rotação desta microplaca, foi
593 teorizada uma microplaca extra, chamada de Microplaca Patagônica. Esta
594 microplaca Patagônica era provavelmente conectada com a Microplaca Lafonia
595 através de uma grande zona de cisalhamento dextral. Provavelmente, esta falha,
596 chamada de Sistema de Gastre (Rapela et al., 1991; Rapela and Pankhurst, 1992),
597 foi essencial agente de transporte da Microplaca de Lafonia. Marshall (1994),
598 partindo desta premissa, propôs que ela deveria ser desconectada do Maurice
599 Ewing Bank (Barker et al., 1977a) e então rotacionada. Diversos autores amarraram
600 estes eventos entre 190 e 130 Ma (Barker, 1999; Stone et al., 2009; Storey et al.,
601 1999; Thomson, 1998). No entanto, observando diversos padrões de rifteamento nas
602 bacias de Outenika e *Northern Falkland (Malvinas) Basin*, Thomson (1998) limitou
603 este período ao Valengiano (≈ 134 Ma).

604 Da mesma forma que o modelo de Du Toit, há ambiguidades neste modelo de
605 reconstrução. A estratigrafia, incluindo suas descontinuidades, é similar entre as
606 unidades expostas na Sierra Pillahuincó e Sierra de La Ventana (Pankhurst et al.,
607 2006). Ainda, a assembléia Malvinokafrica se estende não somente nas Ilhas
608 Falkland (Malvinas), mas também na Bacia do Paraná (Clarke, 1913), Patagônia
609 (Manceñido and Damborenea, 1984), prisma acrescionário do Chile (Fortey et al.,
610 1992), além do já citado *Cape Fold Belt*. As glaciações do Eo-paleozóico e a direção

611 do fluxo das geleiras são similares aos depósitos glaciais do centro da Bacia de
612 Tepuel-Genoa (Griffis et al., 2014). Além disso, a vergência observada nas ilhas é
613 diferente da vergência catalogada tanto no Cape Fold Belt, quanto no Sierra de La
614 Ventana Fold-belt; no entanto, conforme apontado por Ramos et al. (2017) possui o
615 mesmo *trend* observado em quartzitos na Patagônia (von Gosen, 2003).

616 O principal ponto fraco da hipótese de Adie é a necessidade de uma rotação
617 de 180° das ilhas em tempos pré-Jurássicos, de maneira a acomodar as
618 similaridades já citadas. Ramos et al. (2017) apontaram que, apesar de robusta, a
619 correlação entre as Ilhas Malvinas e África do Sul não consiste de única solução
620 para a problemática da evolução da região e mostram que há similaridades
621 importantes com a Patagônia que não devem ser descartadas.

622 3.4.3 Hipótese de Borello (1963)

623 Borello (1963) apontou diversas similaridades das Ilhas Falkland (Malvinas)
624 com o terreno Patagônico. Ramos et al. (2017) mostraram, através de uma
625 excelente revisão bibliográfica, seguida de um estudo isotópico e de proveniência, a
626 importância de considerar o terreno setentrional sul-americano nas reconstruções.

627 É demonstrado, por exemplo, que o Sistema Gastre não possui evidências de
628 cisalhamento dextral. De maneira oposta, é um sistema de falhas reversas com um
629 componente sinistral subordinado (Franzese e Martino, 1998; Ramos et al., 2017).
630 Provavelmente, esta zona de falhas reversas dúcteis está restrita ao Paleozóico, não
631 podendo ser mais jovens que o Permiano. Portanto, os dados de Franzese e Martino
632 (1998) e von Gosen e Loske (2004) não corroboram à existência de um sistema de
633 cisalhamento dextral intracontinental, tal qual concebido por Rapela et al. (1991) e
634 Rapela e Pankhurst (1992), que acomodasse os movimentos necessários à rotação
635 das Ilhas Falkland (Malvinas; Ramos et al., 2017). Desta forma, Ramos et al. (2017)
636 concordam com o inicialmente proposto por Rabinowitz e LaBrecque (1979), onde a
637 zona de falha da Agulhas/Malvinas, transformante em essência, foi de vital
638 importância à separação do Falkland (Malvinas) Plateau do Agulhas Plateau. Esta
639 falha foi ativa durante a abertura do Atlântico Sul e, do lado sul-americano,
640 desaparece em direção ao continente.

641 Ainda, há duas populações de diques doleríticos, com idades do Eo-Jurássico
642 e Eo-Cretáceo, respectivamente (Cingolani e Varela, 1976; Hole et al., 2015; Mitchell

643 et al., 1986; Mussett e Taylor, 1994; Richards et al., 2012; Stone et al., 2009, 2008).
644 O mais antigo, Eo-Jurássico, possui um *trend* direcional que sugere esforços
645 extensionais de natureza NE-SW; enquanto que os Eo-Cretáceos possuem
646 esforços de natureza E-W. Conforme apontado por Ramos et al. (2017), o evento
647 Jurássico é provavelmente resposta à abertura do Mar de Wedell, enquanto que o
648 evento Cretáceo ocorreu devido à abertura do Atlântico Sul. Evidências destes
649 episódios são encontradas em bacias *offshore*, por exemplo *Southern Rift System*
650 (NW-SE) e *North Falkland (Malvinas) Basin* (N-S; Richards et al., 2012). Assim
651 sendo, os esforços Mesozóicos das ilhas são predominantemente puros e, devido a
652 isso, podem ser associados a esforços de mesma natureza e idade encontrados na
653 Patagônia. Desta forma, é possível relacionar a mudança de tensões a episódios
654 tectônicos de escala continental distintos, ao invés da rotação do bloco.

655 De maneira a corroborar à hipótese de Borello (1963), Ramos et al. (2017),
656 fazendo um estudo de proveniência de unidades Siluro-Devonianas pós
657 desconformidade, identificaram uma assinatura Neo-Cambriana-Ordoviciano nos
658 zircões. Esta assinatura é comum em quartzitos do sistema Sierra de La Ventana
659 (Alessandretti et al., 2013). Provavelmente, são derivados de rochas ígneas de
660 mesma idade advindas do Maciço Deseado (Moreira et al., 2013). Não há rochas
661 com essas idades advindas do sistema *Cape Fold Belt*, nem de *Maud Belt*. A
662 assinatura das rochas do Natal, no entanto, é marcada por zircões Neo-, Meso- e
663 Paleoarqueanos (Ramos et al., 2017).

675

676

Highlights:

677

- Maurice Ewing Bank Complex underwent collisional granulite facies metamorphism, with associated partial melting, related to Rodinia-Forming orogeny;

678

- Paragneiss protolith deposited in a back-arc environment, with sediments transported from Margate-Maurice-Sivorg volcanic arc and Kaapvaal-Grunehogna craton;

679

680

- 4 episodes of recrystallization-partial melting are related to Rodinia forming orogens. The climax (R3) occurred close to the Stenian-Tonian boundary at 1 Ga, causing the peak metamorphism recrystallization event not only in Maurice Ewing Bank, but also in Natal Province, and Cape Meredith Complex;

681

- Maurice Ewing Bank constitutes a link between Natal and Maud belt. Therefore, it is part not only of Kalahari Craton but also of Grenville orogeny.

682

683

- Natal-Maud belt were generated due to the interaction of Patagonia-Coats land and Kaapvaal-Grunehogna margins;

684

685

686

687

- The complex underwent several thermal reactivations, up-to greenschist facies, related to Neoproterozoic and Paleozoic events such as Panantartican-Panafrican, and Gondwanides.

697

ABSTRACT

698 The evolution of Rodinia still have several questions that remain *incognito*, which
699 directly impact the paleotectonic interpretation of coeval and posterior events. That is
700 the case of the role of the unexposed Mesoproterozoic crust of remnant micro-
701 terranes such as Maurice Ewing Bank and its relationship with the Rodinia-forming
702 process at ca. 1 Ga. This works aims, by means of petrology and geochemistry, to
703 unravel the metamorphic history of the Maurice Ewing Bank Complex (MEBC), and
704 to determinate its role in the Laurentia-Kalahari evolution. MEBC consist of a
705 polyphasic metamorphic terrane with three recrystallization cycles. The Rodinia-
706 forming cycle (R) has one episode of deposition and four episodes of
707 recrystallization/progressive deformation identified: [1] deposition of immature
708 sediments, in a back-arc environment, close to the source rock (R0); [2 and 3] long-
709 lasting high-temperature, high-pressure metamorphic condition, related with a fold-
710 and-thrust belt (R1-R2). [4] granulite facies metamorphism (R3). [5] end of the
711 collisional event, characterized by post-deformational granitoids (R4). We interpret
712 that R1-R2 coincides with the older syn-deformational metagranitoid age of $1068 \pm$
713 28 Ma. A tectonic exhumation in R3 is related to syn- to tardi-metagranitoids at 1032
714 ± 12 Ma. It was followed by an R4 event of crustal delamination at 1006 ± 13 Ma. The
715 reset in Rb-Sr and K-Ar systems were due to posterior metamorphic cycle, up to
716 greenschist facies ($<500^{\circ}\text{C}$). We interpret that as caused by far-field thermal
717 anomalies of Neoproterozoic-Paleozoic orogenic events, such as Panantartican-
718 Pananfrican-Gondwanides. The anchimetamorphic cycle ($<300^{\circ}\text{C}$) is related to
719 uncomprehend Juro-Cretaceous rifting events. MEBC was part of Natal-Maud
720 orogeny by the end of Mesoproterozoic, standing right in between Margate and
721 Heimefrontfjella terranes. We suggest that the collision of Kaapvaal and Coats-
722 Patagonia margins generated Natal-Maud belt, including MEBC. The true extension
723 of the collision could be extrapolate far west the Beattie-A anomaly, ending close to
724 the Chilenia-Cuyania-Llano at Laurentia.

730 **1 INTRODUCTION**

731 Rodinia is a powerful polysemic Russian word (McMenamin and McMenamin,
732 1990). It means what it means: *to beget* or even *to grow*. By doing so, this word
733 represents not only procreation but also the natural development of maturity (Li et al.,
734 2008). Notwithstanding, in Earth Sciences, Rodinia represents a hypothetic
735 configuration of land masses that perpetuated from Mesoproterozoic (≈ 1.1 Ga) to
736 Neoproterozoic (≈ 0.7 Ga; Nance et al., 2014; Roberts, 2013; Roberts et al., 2015).
737 Rodinia-forming event had reached its apex around Stenian-Tonian period when
738 several continental blocks amalgamate to form a supercontinent through continental-
739 wide orogenic events (*a.k.a Grenville Event*; Li et al., 2008; Roberts et al., 2015).
740 Today, several available reconstruction models represent this cycle. These models
741 surround the threshold between creativity and scientific knowledge. Unfortunately,
742 they only consider large cratonic areas. As expected, several units of geological
743 relevance have not been considered in paleogeographical reconstructions whether
744 their limited areal extent or complete geological unawareness (Fuck et al., 2008; Li et
745 al., 2008). In other words, many of Rodinia continental “*heir*” is still considered
746 “*bastards*.”

747 Ignore these still illegitimate terranes, such as Falkland (Malvinas) Island,
748 might lead to conflicting interpretations about Earth evolution. Despite its active role
749 for the consolidation of Continental Drift Theory and Gondwana evolution (Du Toit,
750 1927, 1937), there is still no consensus about Falkland (Malvinas) Island position
751 before Gondwana break-up. According to Ramos et al. (2017), there are three main
752 hypotheses about the tectonic evolution of the island. Du Toit (1937) argued that the
753 island was somewhere between South America and South Africa. Contrastingly, Adie
754 (1952) inverted the position of the island, placing it as an appendix of Cape Fold Belt,
755 in South Africa east side. Borello (1963) theorized that the island kept a similar
756 position as seen today, standing fixed to the South American plate. However, as
757 pointed out by Ramos et al. (2017), one effective way to reduce the several degrees
758 of freedom related to all interpretations is increase the knowledge about Maurice
759 Ewing Bank continental basement.

760 This feat has only made possible due to the *Deep-Sea Drilling Program*
761 (DSDP), which was, coincidentally proposed by Dr. Maurice Ewing (Ewing and

762 Hayes, 1970). In 1974, DSDP leg 36 was planned to clarify the geologic history of the
763 southwest Atlantic Ocean, and Falkland (Malvinas) Plateau (Barker et al., 1977b).
764 During the expedition, lousy weather condition led to a re-evaluation of the selected
765 sites, which ironically resulted in the drilling of site 330 (Barker et al., 1977b). After
766 2626 m of the water column, and 550 m of Mesozoic-Cenozoic sedimentation, 19.5
767 m of the gneissic and granitic continental basement were drilled that comprehend the
768 only physical register of a whole crustal block (Tarney, 1977; Figure 1 - B).
769 Beckinsale et al. (1977) had dated these rocks as Ediacarian-Fortunian (Rb-Sr, and
770 K-Ar), and interpreted them as a thermal reactivation event during Paleozoic.
771 Nonetheless, the scientific community considered those ages as crystallization
772 events, which led to several misinterpretations about the Falkland (Malvinas) Plateau
773 evolution. Recently, Chemale Jr. et al. (2018), using U-Pb in zircon, reinterpreted the
774 age of Maurice Ewing basement rocks as metamorphosed and, when applicable,
775 generated by a Stenian-Tonian age regional event. This fact led to a debunking of
776 the region, relating Maurice Ewing Bank rocks with Cape Meredith Complex, located
777 at Falkland (Malvinas) Islands (see Chemale Jr. et al., 2018 for more detail). The
778 petrography aspects, however, were only studied by Tarney (1977), who identified a
779 high-grade metamorphism event. Since Tarney's pioneer study, the rocks have not
780 been revisited.

781 This work aims, by means of petrology and geochemistry, unravel the
782 metamorphic history of the MEBC to determine its role in the Natal-Maud belt, and
783 Greenville orogeny. Furthermore, after an extensive literature review, this work
784 purposes to hypothesize the terranes involved in the Natal-Maud generation to
785 diminish the degrees of freedom derived from Rodinia reconstructions.

786

787 2 REGIONAL FRAMEWORK

788 The Falklands (Malvinas) Plateau is a submarine projection of the South
789 American continental margin that extends through approximately 1800 km east of the
790 Falklands (Malvinas) Islands, where gently pinches out through the Georgia Basin
791 (Figure 1 - A; Kimbell and Richards, 2008). Two continental-wide features bound the
792 Plateau, Falkland-Malvinas Escarpment (FME) and North Scotia Fault Zone (NSFZ),
793 both related with South Atlantic evolution and Pangea Breakup (Ludwig and
794 Rabinowitz, 1982; Rabinowitz and LaBrecque, 1979). There are two remarkable
795 morpho-structural highs located in the central part of the plateau: i) Falkland Islands
796 and ii) Maurice Ewing Bank. Recently, Schimschal and Jokat (2018), after seismic
797 refraction experiments, postulated that both highs are indeed continental crust
798 separated by a rifting event that had caused oceanic spreading before the Mesozoic-
799 Cenozoic filling of the Falkland Plateau Basin (Figure 1 – B).

800

801

802 Figure 1 – Location of DSDP Site 330, Leg 36. A) Falkland-Malvinas Plateau map
 803 with the main geomorphological features (modified from Chemale Jr. et al., 2018); B)
 804 Simplified geological interpretation of A-A' section following Schimschal and Jokat
 805 (2019) scheme. Legend: FMB – Falkland-Malvinas Block, FME – Falkland-Malvinas
 806 Escarpment, MEB – Maurice Ewing Bank, NSFZ – North Scotia Fault Zone.

807

808 Both blocks have physical evidence of this continental crust signature. In the
 809 Falkland Islands side, there is a thin region located at West Island where these
 810 continental crust rocks outcrop. The Cape Meredith Complex (CMC; Adie, 1952;
 811 Baker, 1924) consists of a metamorphosed volcano-sedimentary sequence with ca.
 812 1.1 to 1 Ga crosscut by several anatectic granites from Stenian-Tonian transition
 813 (Jacobs et al., 1999; Thomas et al., 2000, 1997). Similarly, there is a register of
 814 continental crust recovered at Maurice Ewing Bank block, during DSDP Site 330, leg
 815 36 (Barker et al., 1977a). As CMC, MEBC rocks consist of a metamorphosed
 816 volcano-sedimentary complex, with ca. 1.1 to 1 Ga, crosscut by several anatectic
 817 granites from Stenian-Tonian (Beckinsale et al., 1977; Chemale Jr. et al., 2018;
 818 Tarney, 1977, and this work). These similarities led Chemale Jr. et al. (2018) to

819 hypothesize that, before the Mesozoic extension, MEBC and CMC were the same
820 crustal fragment, herein considered Falkland-Malvinas-Maurice Terrane (F2MT),
821 following suggestions first proposed by Tarney (1977). The impact of these recent
822 finds results in a critical review of the role of F2MT during supercontinent cycles
823 associated with Rodinia amalgamation, and Gondwana breakup.

824 Several reconstructions (Bisnath et al., 2006; Bisnath and Frimmel, 2005;
825 Frimmel, 2004; Jacobs et al., 2015; Joachim Jacobs et al., 2008) consider Falkland
826 (Malvinas) Island, and therefore F2MT, as part of Namaqua-Natal-Maud belt (Jacobs
827 et al., 1993). This belt forms a continental-wide continuum of Mesoproterozoic rocks,
828 product of collisional tectonics along the southern portion of Proto-Kalahari Craton
829 (Jacobs et al., 1993; Joachim Jacobs et al., 2008; Thomas et al., 1994). The Natal
830 Province consists of three arc terranes of ca. 1250-1150 Ma, accreted and
831 metamorphosed during 1150-1100 Ma with post-accretion extension at ca. 1080 Ma
832 and post-tectonic magmatism of ca. 1050-1030 Ma (Cornell et al., 2006; Mendonidis
833 et al., 2015a; Mendonidis and Grantham, 2003; Spencer et al., 2015a);
834 Heimefrontfjella, the Dronning Maud Land proxy, represents a complete volcanic-arc
835 system, composed by back-arc basin, volcanic rocks related to the arc itself, and
836 forearc basin sediments with protolith, and maximum deposition ages varying from
837 1200-1100 Ma (Jacobs, 2009; Jacobs et al., 1996). The region underwent two high-
838 grade metamorphism event, related to the orogenic event at ca. 1090- 1060 Ma and
839 ca. 500 Ma (Arndt et al., 1991; Jacobs et al., 2003a; Schulze, 1992). Both provinces
840 have post-deformational rocks from the Tonian-Stenian transition.

841

842 3 RESULTS

843 3.1 Petrography

844 The samples employed for this work consist of 7,2 m of the recovered
 845 basement from the DSDP expedition 330, leg 36, cores 16 – 17 (Barker et al.,
 846 1977a). After the mesoscale description, 22 thin polished sections were made to
 847 understand the relationship between minerals, textures, and their structural/spatial
 848 patterns (Passchier and Trouw, 2005 - more info about sampling, check
 849 Supplementary Material 1). We collected 300 points per sample, at regular intervals
 850 of 1 mm, to obtain the statistic mode (Table 1 – see Supplementary Material 2).

851 Petrographically, the MEBC rocks have five distinct and wide classes,
 852 hereafter considered *sensu lato* lithofacies: (Figure 2 - A) paragneisse, (B) pre-
 853 deformational metagranite, (C) syn- to tardi-deformational metagranite, (D) post-
 854 deformational granitoid, and (E) melanosome (Table 1 - to compare with Tarner,
 855 1974 and Chemale Jr. et al 2018 interpretations Supplementary Material 3).

856

857 Figure 2 - - Lithofacies of Maurice Ewing Bank Complex. A - Paragneisse (#17R2-
 858 06; 0.33-0.40m); B – Pre-deformational metagranite (#16R2-08; 0.50-0.56m); C –
 859 Tardi-deformational granite (17R3-14; 0.83-0.90m); D – post-deformational granite
 860 (#16R2-18; 0.69-0.77m); E – Melanosome (#16R2-11; 0.69-0.77m).

861

862 The lithofacies has medium to coarse-grained crystals, primarily composed by
 863 quartz and feldspars in the quartzo-feldspatic (QF) domain, and biotites in the mafic
 864 (M) domain. The main structure is gneissose, and the main texture is granoblastic.
 865 The sum of these characteristics fits the definition of granulite rock, as suggested by

866 Coutinho et al. (2007). There is a subgroup of this lithofacies, herein classified as
 867 weathered paragneiss. In a broad sense, it contains euhedral diagenetic calcite, and
 868 tabular tourmaline, despite all paragneisses characteristics. As expected in this
 869 lithofacies, there are two main mineralogical domains i) quartz-feldspathic rich (QF),
 870 and ii) mafic rich (M) in a well-formed primary foliation. There is a posterior subtle
 871 foliation, mainly composed by platy biotite crystals, that crosscuts the main foliation.
 872 This feature is indicative of a C-S fabric as already noted by Chemale Jr. et al.,
 873 (2018).

874 The granitoids were classified as pre- (Figure 2 - B), tardi- (Figure 2 - C), and
 875 post-deformational (Figure 2 – D). They vary from very fine to coarse-grained
 876 crystals. In pre-deformational, grains tend to be fine-grained. The dominant crystal
 877 size is medium in tardi-deformational; however, coarse-grained crystals can also
 878 occur. In post-deformational, the crystal size, dominated by alkali feldspars, tends to
 879 be coarse to very coarse.

880 The last unit has a brownish to black color, dominantly composed by relict
 881 biotites, today replaced by green chlorites (Tarney, 1977; Figure 2 – F). All units are
 882 cut to some extent by mm to cm thick subvertical to subhorizontal quartz or calcite
 883 veins. For a description of microtectonics, the reader is referred to Supplementary
 884 Material 4.

885 Table 1 – Summary of mineral assemblage and accessories according to each
 886 lithofacies.

Lithofacies	Paragenesis	Accessories
Paragneiss	Qtz + Kspar + Plag + Grt ± Sil ± Tour ± Cal	Rut + Ap + Zrc + Mon
Pre-deformational metagranite	Qtz + Kspar + Bt + Sil + Grt + Plag ± Cal ± Chl	Chl + Ap + Zrc + Mon
Syn- to Tardi- deformational metagranite	Kspar + Qtz + Plag + Bt + Grt ± Chl	Chl + Ap + Zrc + Mon
Post-deformational Granitoid	Kspar + Qtz + Bt	Chl + Ap + Zrc + Mon
Melanosome	Bt + Chl + Qtz	Rut

887 3.1.1 Paragneisses

888 The metasedimentary rocks were classified as paragneisses and weathered
 889 paragneisses, following the suggestions of Schmid et al. (2007). Generically, this unit

890 is dominantly composed by quartz, alkali-feldspar, with minor plagioclase, and
891 sillimanite in the QF domain. Biotite mainly composes the mafic domain. Garnet does
892 also occur in the interface between QF, and M. Common accessories are zircon,
893 tourmaline, rutile, ilmenite, and apatite.

894 The quartz crystals tend to be allotriomorphic and granoblastic; while the
895 potassic feldspars are tabular and hypidiomorphic, being recurrently sericitized. The
896 tabular plagioclase, usually sericitized and calcitized, forms a minor constituent. The
897 overall plagioclase composition ranges from Ab_{10-20} (Beckinsale et al., 1977). This
898 high albite content is usually related to retrometamorphism in green-schist facies
899 (Moody et al., 1985).

900 The garnet porphyroblasts, usually located in the interface between QF and M
901 domain, have a variance of textures and geometries. The dominant one consists of
902 blastoid idiomorphic; nonetheless, some allotriomorphic minerals are present, as well
903 as minerals with core-and-mantle texture. Moreover, some garnet crystals are relict,
904 being partially or entirely substituted by biotite/chlorite. In a broad sense, they have a
905 uniform grain size and are usually fractured, with sparse inclusions of quartz, rutile,
906 biotite, ilmenite, and zircon. The occurrence of anomalous size grains is indicative of
907 crystal amalgamation, and thus, rapid growth rate.

908 There are several occurrences of Al_2SiO_5 polymorph sillimanite and fibrolite,
909 demonstrating two different stages of growth with distinctive stress fields. Sillimanite
910 has a bladed geometry oriented according to mineral lineation. The fibrolite is either
911 oriented according to the mineral lineation or randomly arranged in fabric, even
912 occurring as a radiate pattern.

913 The M domain is composed of mm-thick layers mainly formed by idiomorphic
914 biotite. Those micas usually have a hexagonal habit, a characteristic reddish-brown
915 color, preferential intergrown at {001}, and several rutile inclusions. Those inclusions
916 fill the sagenic texture; that is, the rutile needles follow biotite {001} crystallographic
917 plane and are parallel to the {011} crystallographic axis (Shau et al., 1991). The
918 reddish-pleochroism from biotite usually is related to high Ti content. The enrichment
919 of this element is indicative of high-grade rocks, usually related to granulite terranes.
920 The sagenic texture, however, is indicative of retrogressive metamorphism back to
921 green-schist facies (Shau et al., 1991).

922 Calcite occurs only close to the disconformity, between grain aggregates, as a
923 product of plagioclase weathering or recrystallization. The presence of this mineral

924 attests a subaerial period in which MEBC rocks were exposed, a fact already
925 postulated by Tarney (1977).

926 3.1.2 Pre-, syn- to tardi-, and post-deformational granitoids

927 We classify the granitoid rocks into three units, due to their petrographic
928 characteristics: i) pre-deformational; ii) syn- to tardi- deformational; iii) post-
929 deformational. The term proposed by Tarney (1977; e.g., σ_1 , σ_2 , and so forth) will be
930 excluded to avoid jargon misunderstandings. The pre- and syn- to tardi-deformational
931 rocks are placed according to the primary foliation of the paragneiss. The post-
932 deformational, albeit, does not. Still, pre-deformational and syn- to tardi-
933 deformational have a distinctive mineral lineation that coincides with those observed
934 in the gneissic rocks, which was partially obliterated due to static recrystallization
935 processes. The post-deformational granitoids, again, do not have this preferential
936 alignment. Therefore, pre-, syn- to tardi-granitoids are in essence metamorphic;
937 whilst post-deformational granitoids are igneous.

938 The quantity of each mineral is variable. Nonetheless, the rocks have an
939 evolutionary trend ranging from granites and sienogranites (pre-deformational and
940 syn- to tardi-deformational) to sienites (post-deformational). All granitoids but post-
941 deformational, are composed by potassium feldspar, plagioclase, quartz, and
942 biotites. The post-deformational lacks plagioclase, being only constituted by
943 potassium feldspar, quartz, and biotite. Accessories minerals, disregarding their
944 lithofacies, are zircon, apatite, ilmenite, and monazite.

945 Alkali feldspars range in size from fine- to medium-grained, in pre-
946 deformational and tardi-deformational to very-coarse in post-deformational. Usually
947 hypidiomorphic, they have two distinct populations: microcline and sanidine. This
948 contrast is related to fractures regions. Microcline only occurs at high-strained
949 locations. Plagioclases, usually with albite twinning, are dominantly hypidiomorphic,
950 ranging from fine to medium grained. Commonly, they are sericitized. Plagioclases
951 from pre-deformational and tardi- post-deformational have different compositions.
952 The pre-deformational has a slightly more sodic composition, whereas tardi- post-
953 deformational, more calcic. Quartz crystals vary from very fine to coarse and are
954 usually allotriomorphic with undulose extinction. Biotite is the only mafic forming
955 mineral identified in all granitoids. The biotites crystals share those characteristics

956 identified in paragneisses (i.g. hypidiomorphic, reddish pleochroism, sagenitic
957 texture).

958 Unlike post-deformational granitoids, pre-deformational meta-granitoid has
959 tabular sillimanite and acicular fibrolite. Still, both pre- and syn- to tardi-deformational
960 have granoblastic garnet inserted in a matrix that was affected by some extend to
961 ductile processes. These data suggest that the metamorphic peak affected not only
962 paragneisses but also those two granitoid units.

963 3.1.3 Melanosome

964 This lithofacies dominantly consists of relict idiomorphic biotites. Today, biotite
965 crystals are weathered to a greenish-clay mineral and unweathered reddish-brown
966 biotites. The relict idiomorphic biotites usually have a hexagonal habit, a
967 characteristic green color, and preferential intergrown at {001}. The reddish-brown
968 biotites share the characteristics from other units (e.g., sagenitic texture). Thus,
969 acicular rutile is a common accessory. There are no expansive clay minerals
970 identified in this lithofacies. However, the greenish-clay mineral identified by Tarney
971 (1977) consists of corrensite, a chlorite mineral (Supplementary Material 5).

972

973 Figure 3 – Thin section of Maurice Ewing Bank Complex lithofacies. A – Paragneiss;
974 B- Pre-deformational metagranite; C – Syn- to Tardi-deformational metagranite; D –
975 Post-deformational sienite; E – Melanosome.

976

977 3.2 Geochemistry

978 Sample preparation and rock chemical analyses were made at Activation Labs
979 for major, and trace elements. The acquired geochemistry results obtained by Tarney
980 (1977) were assembled to our database to build a better statistical framework
981 (Supplementary Material 6). The statistical sample was made using GCDKit software
982 (Janoušek et al., 2006) as well as the plotting of several geochemical diagrams.
983 When applicable, all samples were prepared considering a volatile free environment,
984 normalized to 100% total (Verma and Armstrong-Altrin, 2013). We utilized diagrams
985 proposed by Herron (1988), Roser and Korsch (1988), and Verma and Armstrong-
986 Altrin (2013) to understand the composition of protolith, in the rocks that have
987 sedimentary derivation (e.g., paragneisses and weathered paragneisses). Those
988 diagrams consist of the analysis of major and trace element concentrations to infer,
989 respectively, the initial sedimentary composition, the provenance, type of source-
990 area, and the geotectonic environment.

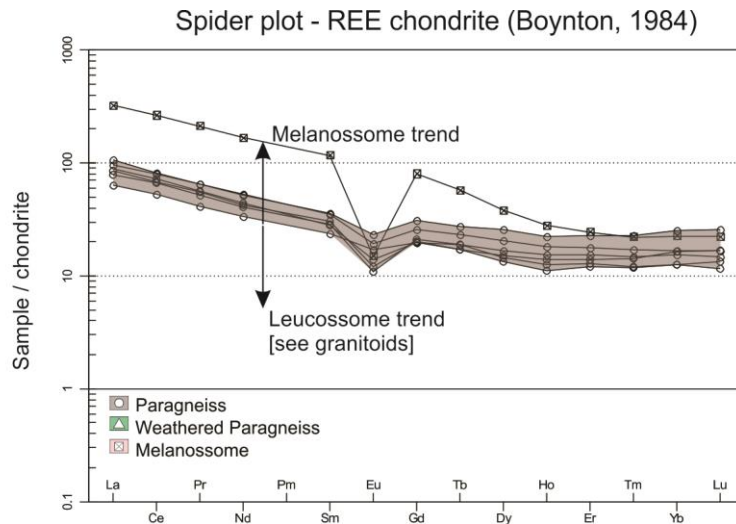

991 The criteria for lithofacies identification was based on major and trace element
992 analysis (e.g., chondrite REE normalized diagram from Boynton, 1984). As
993 petrography analysis, we interpreted 5 classes consisting of: i) paragneiss (non-
994 weathered and weathered); ii) pre-deformational metagranite; iii) tardi-deformational
995 granite; iv) post-deformational granite; and v) melanosome.

996 3.2.1 Paragneisses

997 The paragneisses share most of the oxide composition, despite being
998 separated into two sub-groups. They have high SiO₂ content ranging from 58 to 82
999 wt%. The Al₂O₃ content is highly variable, ranging from 6 to 18.4 wt%. The TiO₂ is
1000 low (0.591 to 1.31 wt%), as well as FeO (0.68 to 4.1 wt%), Fe₂O₃ (1.7 to 5.87 wt%),
1001 MgO (0.28 to 2.16 wt%), MnO (0.01 to 0.16 wt%). The alkalis are relatively low. NaO
1002 ranges from 0.6 to 2.02 wt%, and K₂O from 1.23 to 6.58 wt%. CaO ranges from 0.24
1003 to 9.55. We classify the paragneisses with high CaO content as weathered
1004 paragneiss sub-group, following Tarney (1977).

1005 The chondrite normalized patterns of REEs showed enrichment of LREEs over
1006 HREEs with LaN/YbN = 3.82 – 6.30. All analyzed samples have a strong enrichment

1007 in light rare elements (LREE; $LaN/SmN = 2.69 - 3.02$), flat HREE ($GdN/YbN = 1.21 -$
 1008 1.52), and subtle Eu anomaly ($Eu/Eu^* = 0.65 - 0.78$; Figure 4 - A).

1009

1010 Figure 4 – REE Chondrite (Boynton, 1984) for MEBC paragneisses and
 1011 melanosome.

1012

1013 In a broad sense, the paragneisses are related to immature rocks. The
 1014 protolith varies in composition from psammitic to pelitic in composition. There is a
 1015 predominance of wackes, litharenites, and arkoses (Figure 5 – A). Also, by using the
 1016 major element analysis diagram from Roser and Korsch (1988; Figure 5 – B), all
 1017 paragneisses fit into the recycled-orogenic field, whereas in tectonic discriminant
 1018 diagram, the samples fit into the arc/collisional environment (Figure 5 – C).

1019

1020

1021 Figure 5 – Protolith initial composition diagrams. A) Diagram to discriminate the
 1022 protolith composition (Herron, 1988); B) Provenance diagram based on the
 1023 distribution of major elements (Roser and Korsch, 1988); C) Diagram to discriminant
 1024 the geotectonic environment, based on major element analysis, prior to Cambrian
 1025 period, for rocks with >63 wt% SiO_2 (Verma and Armstrong-Altrin, 2013).

1026

1027 3.2.2 Granitoids

1028 We discriminate three classes of granitoids based on geochemistry, following
1029 petrography analyses. They are pre-, syn- to tardi-, and post-deformational. The SiO₂
1030 from pre-deformational ranges from 70.1 to 71.88 wt. %. The tardi-deformational
1031 granites are slightly richer in SiO₂ content, with values ranging from 66.3 to 73.9 wt.
1032 %. In the post-deformational, similar values for SiO₂ are present, from 63 to 72.83 wt.
1033 %. TiO₂ tends to have lower values in pre-deformational granites than others. Al₂O₃
1034 has values that range from 12.98 to 14.3 wt.%, 11.86 to 15.6 wt. % and 7.05 to 21.6
1035 wt. % in pre-, tardi-, and post-deformational, respectively. K₂O tends to become
1036 enriched according to the fractioning varying from 5.65 to 5.92 wt% in the pre-
1037 deformational, 6.42 to 8.61 wt.% in the tardi-deformational, and 4.39 to 10.94 wt% in
1038 the post-deformational granite. The CaO has a composition from 0.31 to 0.52 wt. %,
1039 0.27 to 1.00 wt% (with an outlier of 6.72) and 0.51 to 0.77 wt%.

1040 The chondrite-normalized REE pattern for the pre-deformational metagranite
1041 is similar to paragneisses (Figure 6 – A). There is an enrichment of LREE over HREE
1042 (La_N/Yb_N = 4.74) as well as enrichment in LREE (La_N/Sm_N = 3.16), flat behavior in
1043 HREE (Gd_N/Yb_N = 1.13), and subtle Eu anomaly (Eu/Eu* = 0.63). In tardi-
1044 deformational granites, the LREE pattern and Eu anomaly are similar to either
1045 paragneisses or pre-deformational meta granites (La_N/Sm_N = 2.39 – 2.66; Eu/Eu* =
1046 0.5 – 0.88); however, there is a strong enrichment of LREE over HREE (37.08 – 106-
1047 52) and HREE depletion (Gd_N/Yb_N = 10.29 – 25.02). The post-deformational granite
1048 has the lowest LREE normalized values. Despite the overall low LREE content, this
1049 unit follows the trend of MEBC (La_N/Sm_N = 2.81 – 3.22). However, two main
1050 contrasting characteristics emerge i) lack of Eu anomaly (Eu/Eu* = 1.04 – 1.13) and
1051 ii) moderate HREE depletion (Eu_N/Yb_N = 3.98 - 5.97). We interpret that the REE
1052 pattern has similarities of arc granitoids, being generated during the first anatectic
1053 pulses. Therefore, pre-deformational metagranite is probably the older migmatized
1054 unit in the complex. Both sin- to tardi-deformational have a REE pattern similar to sin-
1055 to post-orogenic granitoids. In post-deformational granite, the strong HREE depletion
1056 probably reflects the lack of metamorphic minerals (e.g., garnets) in the assemblage,
1057 and thus the absence of metamorphism. We interpret the lack of Eu anomaly and the
1058 depletion of HREE as generated due to pegmatitic placement (Tarney, 1977). Thus,

1059 post-deformational granite is the youngest rock of the unit, probably generated close
 1060 to the liquidus-out in the system.

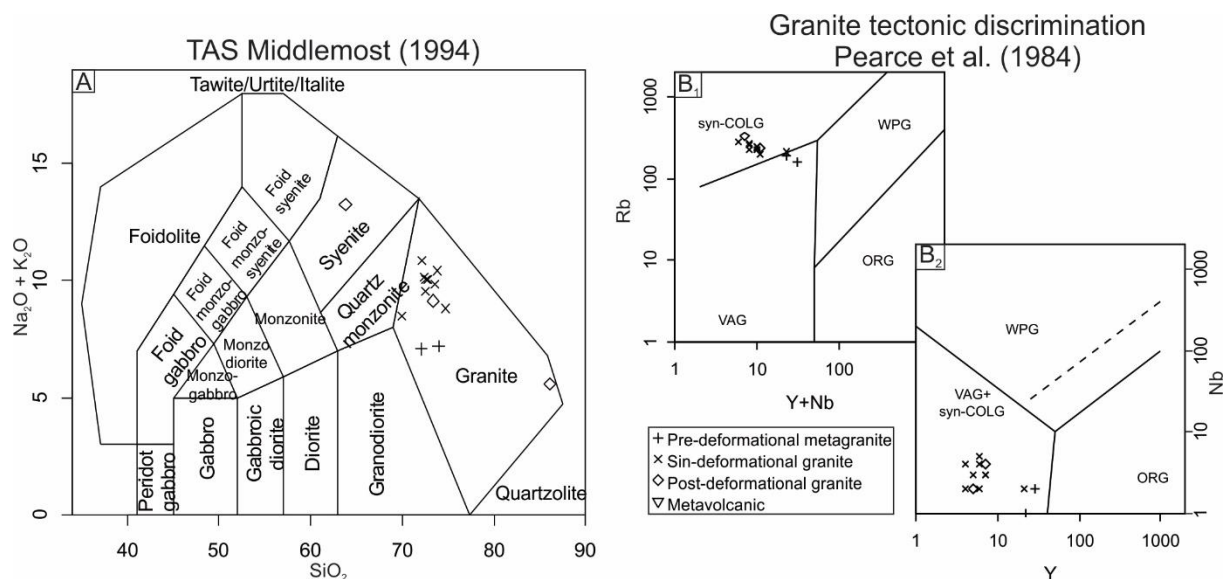

Figure 6 - REE Chondrite (Boynton, 1984) for MEBC granitoids.

1064 There is a compositional evolution pattern from pre- to post-deformational
 1065 granites. According to Middlemost (1994) classification diagram (Figure 7 – A), we
 1066 classify the pre- and tardi-deformational granitoid as granites. The post-deformational
 1067 granite, however, ranges from granite to syenite. In the Rb vs. Y+Nb diagram, pre-
 1068 deformational metagranite falls into VAG field; whereas the other granites in the syn-
 1069 COLG field (Figure 7 - B1). On the other hand, all granites fall into Volcanic Arc
 1070 Granites (VAG) + syn- to tardi-collisional granite (syn-COLG) in Pearce Y-Nb tectonic
 1071 discrimination diagram (Figure 7 – B2). Therefore, pre-deformational metagranitoid
 1072 was generated in an arc environment; whereas, syn- to tardi-, and post-deformational
 1073 were generated in a collisional setting. There is an agreement between geochemical
 1074 and petrological description, thereby validating the interpretation. The granite
 1075 samples preserved the expected characteristics of thermal/anatectic pulses, being
 1076 useful markers for the tectono-thermal evolution of the complex (Chemale Jr. et al.,
 1077 2018).

1081

3.2.3 Melanosome

1082

1083

1084

1085

1086

1087

1088

The melanosome lithofacies has a composition that suggests a high incompatible enrichment. SiO_2 is low, with a value of 39.15 wt%, whereas Al_2O_3 is high (22.03 wt.%). TiO_2 is also high, with 2.21 wt%, as well as Fe_2O_3 (17.05 wt%) and MgO (2.97 wt%). CaO and NaO have respectively low values of 0.29 and 0.54. K_2O is high with a value of 5.14. Al_2O_3 , K_2O , and TiO_2 enrichment are mainly due to the quantity of Ti-rich biotites. The lack of silicic minerals, such as feldspars, reflects the SiO_2 abundance.

1089

1090

1091

1092

1093

1094

1095

1096

1097

1098

There is a fractionated pattern with the highest identified REE abundances ($\text{La}_N/\text{Yb}_N = 14.34$) compared to the other rocks of the MEBC. The unit has a strong enrichment in LREE ($\text{La}_N/\text{Sm}_N = 2.78$), moderate enrichment in HREE ($\text{Gd}_N/\text{Yb}_N = 3.55$), and strong Eu anomaly ($\text{Eu}/\text{Eu}^* = 0.15$) when compared to paragneiss. The normalized chondrite patterns of REEs of this unit is somewhat similar to the paragneisses but enriched in all aspects. Additionally, it has a strong Eu anomaly (Figure 4). Both data confirms that this lithofacies is indeed a melanosome, being enriched in LREE and MREE, in this case liquidus incompatible, and highly depleted in Eu.

1099 3.3 Mineral Chemistry

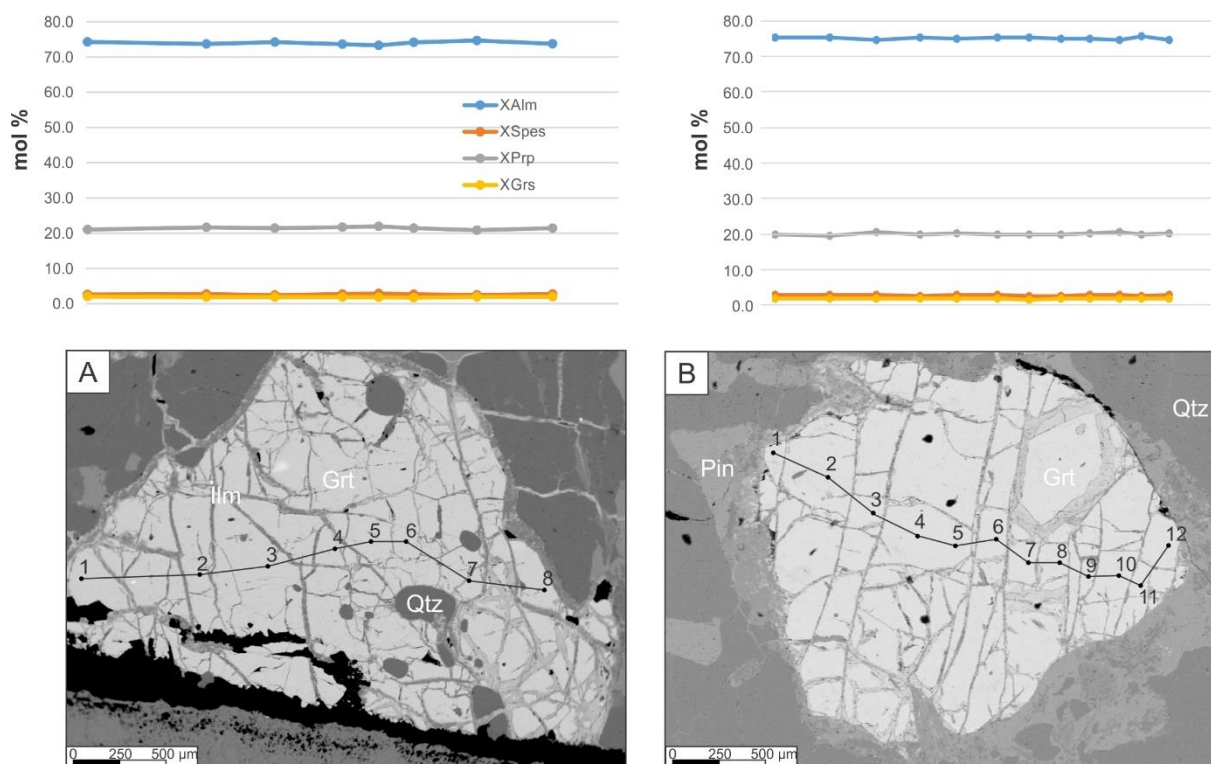

1100 Mineral chemical data were obtained with an electron microprobe JEOL JXA-
 1101 8230 with one EDS and five WDS spectrometers, at the Instituto de Geociências da
 1102 Universidade de Brasília, operating at 15kV and 15nA. Major elements were
 1103 calculated in garnet, white mica and biotite, plagioclase, alkali feldspar, opaques
 1104 (e.g., mostly magnetite and ilmenite), chlorite, and tourmaline, despite the rock unit.
 1105 The garnet was normalized to 12 oxygens. Additionally, a stoichiometric calculation
 1106 was done to convert Fe_{total} to Fe_2O_3 and FeO . The mica group minerals were
 1107 normalized to 11 oxygens, and its H_2O amount in the system estimated considering
 1108 that $OH + Cl + F = 2$. The feldspars group were normalized to 8 oxygens. The
 1109 software WinCCac (Yavuz et al., 2015) processed the data regarding chlorite
 1110 minerals. The software calculated the amount of H_2O in each sampling, considering
 1111 14 oxygens in chlorite structural formula. Fe^{3+} was not calculated. We applied the Al_{IV}
 1112 geothermometer proposed by Kranidiotis and MacLean (1987), widely used when
 1113 chlorites that are associated with other alumino-silicates (Yavuz et al., 2015;
 1114 Supplementary Material 7). The software WinTCal (Yavuz et al., 2014) processed the
 1115 data acquired for tourmaline group minerals. The data was normalized to have either
 1116 15 cations at T + Z + Y position or the sum of $OH + F + Cl = 4$. The software
 1117 estimated either Fe^{3+} content according to the normalization to $O_{24.5}$ or H_2O content
 1118 (Supplementary Material 8). The calculation for end-members was made according
 1119 the following formulas: (i) Garnet $X_{Alm} = Fe_{2+} / (Fe_{2+} + Mg + Mn + Ca)$, $X_{Py} = Mg /$
 1120 $(Fe_{2+} + Mg + Mn + Ca)$; $X_{Gr} = Ca / (Fe_{2+} + Mg + Mn + Ca)$; $X_{Sps} = Mn / (Fe_{2+} + Mg + Mn + Ca)$; (ii)
 1121 Feldspars: $X_{An} = Ca / (Ca + Na + K)$; $X_{Ab} = Na / (Ca + Na + K)$; $X_{Kfs} = K / (Ca + Na + K)$.

1122 3.3.1 Garnet

1123 The garnets from MEBC have mean composition of $Fe^{2+}_{2.26}Mn_{<0.01}$
 1124 $Mg_{0.62}Ca_{0.06}Al_{2.03}Fe^{3+}_{<0.01}(SiO_4)_3$ (n=179) and a homogeneous composition. This
 1125 homogeneity is unit independent; that is, it occurs in all lithological units, except
 1126 those that do not have garnets in the system (e.g., melanosome and post-
 1127 deformational granitoid). The crystals are almandine rich, with mean $X_{alm} = 77 \pm 0.12$
 1128 (2σ ; Supplementary Material 9). There is no distinct Zoning from the core to the rim

1129 (Figure 8A and 8B). The garnet composition fits well the garnets derived from
 1130 granulite terranes (Supplementary Material 10).

1131

1132

1133 Figure 8 – Compositional profile of two idioblastic garnets. A) Pre-deformational
 1134 metagranite: fractured garnet porphyroblast with elliptic-shaped quartz inclusions,
 1135 and microinclusions of ilmenite. Additionally, there is a subtle reaction rim formed by
 1136 pinite, a tardi-mineral phase (see text for discussions). B) Tardi-deformational
 1137 granitoid– Fractured garnet porphyroblast with thicker pinite reaction-rim. Note the
 1138 lack of quartz blobs and the presence of micro-ilmenites.

1139 3.3.2 Feldspars

1140 The analyzed feldspars are divided into four groups, three representing the
 1141 alkali feldspars series and one representing the plagioclase series (Figure 9 - A).
 1142 Each group is lithology dependent; that is, formed in a certain lithotype or a
 1143 combination of lithotypes. Feldspars with X_{Or} range from 74 to 99, with a mean ($n=38$)
 1144 of 83 ± 2 (2σ), compose the first group, restrictedly occurring at paragneiss samples.
 1145 The second group occurs in weathered paragneiss and mostly consists of X_{Or} ranging
 1146 from 58.7 to 96.9 with arithmetic mean of ($n=9$) 77 ± 10 (2σ). The third group has an
 1147 arithmetic mean ($n=20$) of 85 ± 3 (2σ), with X_{Or} ranging from 77 to 99, coinciding with
 1148 pre-deformational granites. Rarely, do extreme X_{Or} values occur in this specific group.

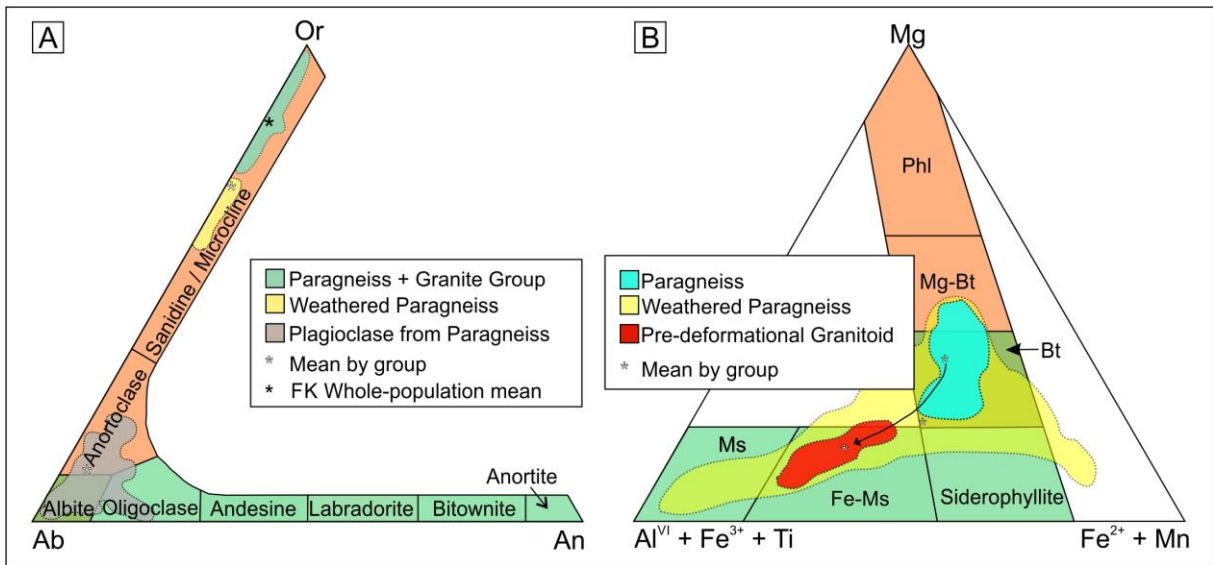

1149 If all alkali feldspars samples are analyzed (n=67). For X_{or} , the arithmetic mean of 85
1150 ± 2 (2σ) is obtained.

1151 The plagioclases range in composition from anorthoclase to albite/oligoclase
1152 with An_{01-20} and Or_{21-23} . $An_{06 \pm 01}$ and $Ab_{83 \pm 02}$ (2σ ; n=35) composes the arithmetic
1153 mean. The high variance observed in the plagioclase composition suggests crystal
1154 instability. Additionally, the low Anorthite content might suggest late albitization,
1155 related to greenschist-facies retrograde metamorphism (Moody et al., 1985;
1156 Supplementary Material 11).

1157 3.3.3 Mica

1158 We identified three distinct classes for micas (Figure 9 - B): i) Mg-rich biotites
1159 to Biotites; ii) Fe-Muscovite micas, and iii) lattice deficient micas. Each group is
1160 lithology-dependent. The Mg-rich Biotite to Biotite group mostly occurs in paragneiss
1161 (n=149), whether weathered or not. They have an X_{Mg} arithmetic mean of 0.46 ± 0.01
1162 (2σ). The Ti (apfu) is considerably high, ranging from near zero to 0.92, with $\bar{x}=0.40 \pm$
1163 0.03 (2σ). On the other hand, in the pre-deformational granites (n=10) does only
1164 occurs "Fe-rich Muscovites", with X_{Mg} ranges from 0.22 to 0.37 and $\bar{x}=0.33 \pm 0.001$
1165 (2σ ; Supplementary Material 12). Despite of being characterized as "Fe-rich
1166 Muscovites", the micas from pre-deformational metagranite are indeed biotites in
1167 either petrographical or chemical aspects. However, their high Ti content pushes
1168 their composition to another field. The compositional contrast between groups I and ii
1169 demonstrates two distinct phases of crystallization. We interpreted the former as
1170 metamorphosed by high-temperature metamorphic processes. The Ti content
1171 present in Biotite crystal lattice might suggest, among other things, high temperature
1172 conditions (Henry, 2005; Henry and Guidotti, 2002). Whilst, the latter (tardi-
1173 deformational granite) is a product of anactetic pulses. The Ti (apfu) varies from
1174 close to zero values to 0.87 with $\bar{x}=0.3 \pm 0.16$ (2σ). Micas found in the melanosome
1175 lithofacies (n=26) have a different composition, while compared to other lithotypes
1176 found in the MEBC. X_{Mg} varies from 0.15 to 0.54, with $\bar{x}=0.35 \pm 0.04$ (2σ). This broad
1177 range confirms the phlogopite composition identified in DRX analysis (Supplementary
1178 Material 5). Additionally, the Ti (apfu) ranges from close to zero values to 0.52 with
1179 $\bar{x}=0.16 \pm 0.07$ (2σ). This difference in composition is largely due to weathering

1180 effects. In this case, relict biotites weathered to either chlorites or mica with deficient
 1181 lattices (Rieder et al., 1998).

1182

1183 Figure 9 A –Ternary feldspar diagram classification (Smith and Brown, 1988). Note
 1184 three populations, two composed by alkali feldspars and one by plagioclase. A color
 1185 field represents each zone. B - Mica classification. Ternary diagram, as proposed by
 1186 Foster (1960). Note three distinct group populations, partially limited by lithological
 1187 units. The group I composes the acquired samples from paragneisses, classified as
 1188 biotites. Group II composes the pre-deformational granitoid samples, mainly
 1189 composed by Fe-Muscovites. Group III composes the mica with deficient lattice
 1190 samples, mostly found in the melanosome lithofacies. Asterisc represents the
 1191 arithmetic mean of each group.

1192 3.3.4 Chlorite

1193 Three distinct groups of chlorites were identified related with the MEBC
 1194 lithofacies: i) weathered paragneiss, ii) pre-deformational meta-granitoid, and iii)
 1195 paragneiss. The weathered paragneiss chlorites (n=4) have greater values of H₂O
 1196 when compared to others. Additionally, they have distinct values of Fe²⁺, Mg, while
 1197 almost negligible Mn. Pre-deformational meta-granitoid chlorites (n=5) lacks Mn in
 1198 their lattice; also, they have more Fe²⁺ by the spend of less Mg. Chlorites from
 1199 paragneiss have two characteristics: they lack Mg and have moderate values of Fe²⁺,
 1200 while compared to other lithofacies. Following the scheme proposed by Zane and
 1201 Weiss (1998), all chlorites are tri-trioctahedral, because they have R₁₀₋₁₂ (sum of
 1202 octahedral cations), and □₂₋₀ (sum of vacant crystal lattice) According to Yavuz et al.
 1203 (2015) classification scheme, they are considered Chamosites. Noteworthy is the
 1204 variance in Al_{IV} content, that results in contrasting temperatures of stability. The

1205 weathered paragneiss has values varying from 0.23 to 0.48, whereas the pre-
1206 deformational meta-granitoid chlorites and paragneisses have values ranging from
1207 0.42 to 0.65, and 0.85 to 1.05. As a result, the first group has the lowest modeled
1208 temperatures, ranging from 132 to 177°C. The second group has similar
1209 temperatures, varying from 176 to 225°C; whereas the chlorites from the latter have
1210 the greatest temperatures, ranging from 273 to 316°C. We interpret that diagenetic
1211 processes generated the first two group of chlorites. On the other hand, anchi-
1212 metamorphic conditions generated the chlorites from non-weathered paragneiss
1213 (Supplementary Material 6).

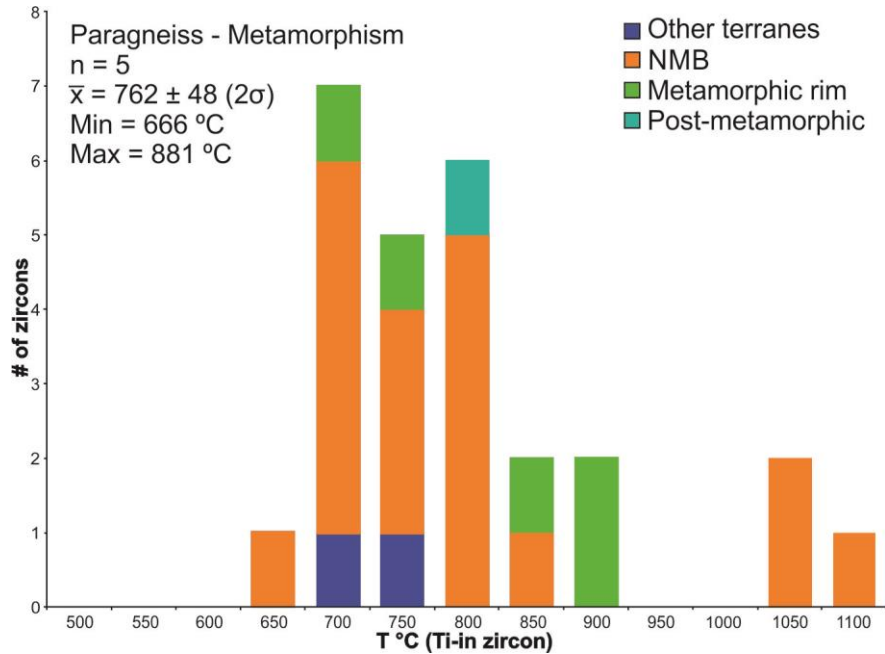

1214 3.3.5 Trace elements in zircon

1215 Trace elements in zircons were determined at Universidade de Ouro Preto by
1216 LA microprobe Photon-machines ArF excimer Laser 193 ($\lambda = 193$ nm) coupled to
1217 Thermo-Fisher Element II sector field (HR-SF-ICP-MS). For a detailed description of
1218 the method, the reader is referred to Andrade et al. (2014). Twenty-six crystals were
1219 analyzed in the paragneiss unit (#17-R2-A from Chemale Jr. et al., 2018). Ti-in
1220 thermometer from Watson et al. (2006) was used to infer the temperature of
1221 metamorphism. We interpret that samples above 1057°C are outliers; probably
1222 originated by magmatic processes. Thus they were disregarded from descriptive
1223 statistics. Mean confidence interval was calculated, assuming a 95% confidence
1224 level. The acquired 207/206Pb ages (2σ) follows Chemale Jr. et al. (2018) analysis.
1225 Detailed values of elements and isotopic ratio are in Supplementary Material 13.

1226 Four zircon ages groups were identified ($n=26$; Figure 10): i) detrital derived
1227 from Calymmian rocks ($n = 2$); ii) detrital derived from Stenian rocks ($n=17$); iii)
1228 metamorphic zircon from Stenian-Tonian ($n = 5$) and iv) post-tectonic zircon ($n=1$)
1229 from Stenian. Due to the nature of the region (i.g. deposition age concordant with
1230 metamorphism), group ii and iii were combined for this interpretation. Groups i and iv
1231 were discarded for this analysis.

1232 After combining all groups, the Ti-in thermometer gave a mean temperature of
1233 762 ± 42 °C ($n = 25$), with maximum and minimum of respectively 1021°C and 642
1234 °C. By combining only group ii and iii, the mean temperature is 765 ± 21 °C ($n = 22$)
1235 with maximum and minimum of respectively 1021°C and 642°C. If only the
1236 metamorphic zircons were considered, the temperature is 762 ± 48 °C ($n = 5$) with

1237 maximum and minimum of respectively 666°C and 881°C. For the latter, we interpret
 1238 the maximum temperature as peak metamorphism temperature, whereas we
 1239 interpret the minimum as the liquidus-out. Likewise, we interpret the mean
 1240 temperature as representative of syn to tardi-tectonic metamorphism; as a result,
 1241 probably related to sin-deformational granite generation.

1242

1243 Figure 10 – Ti-in zircon histogram from paragneiss. Four classes were identified
 1244 according to their ages, our data is concordant with data acquired by Chemale Jr. et
 1245 al. (2018) interpretation. By considering only the data from the metamorphic rim,
 1246 there is an agreement with liquidus-in trajectory throughout metamorphism.

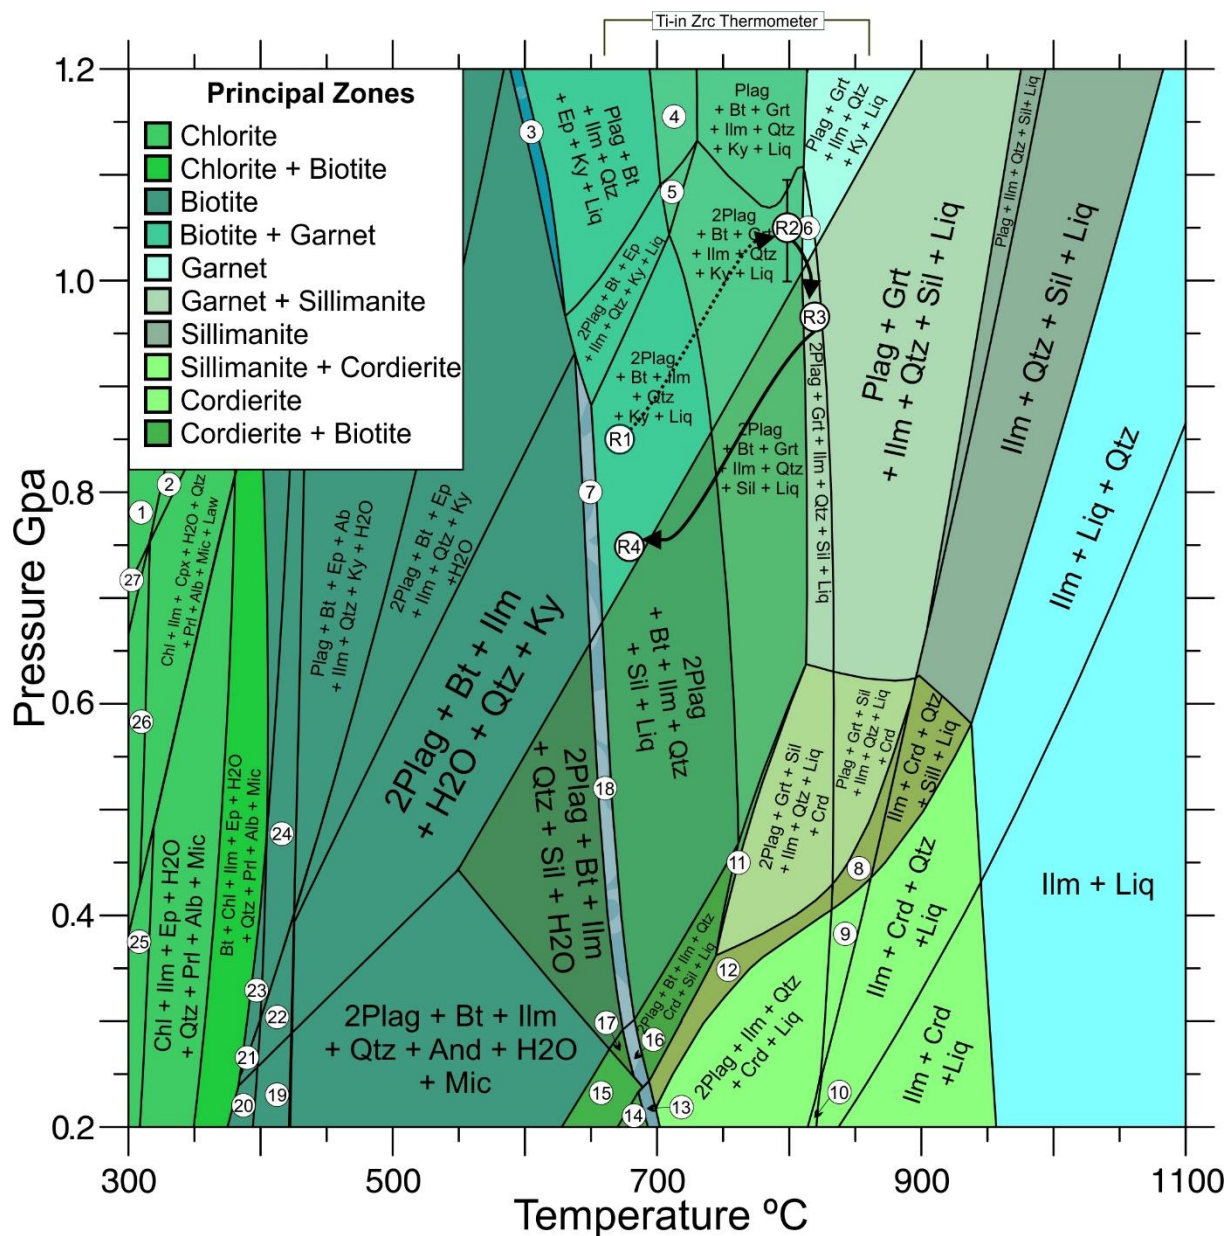

1247

1248 4 MINERAL EQUILIBRIA MODELING

1249 Pseudosection was made using the software Theriak-Domino to get, besides
1250 the PT grids, geothermobarometric interpretation by the isopleth intersection (de
1251 Capitani and Brown, 1987; de Capitani and Petrakakis, 2010). The data-entry was
1252 based on geochemical analysis representing pre-deformational metagranite
1253 lithofacies. The conversion from wt. % to chemical formula was done disregarding
1254 Mn. As a complexing agent, however, Fe^{3+} was considered. Besides, O_2 was
1255 modeled to be free to come and go of the system. Water, on the other hand, was
1256 steady through time, according to the values obtained in the whole rock chemistry
1257 formula.

1258 The thermodynamic equilibrium model here utilized was $\text{K}_2\text{O-FeO-MgO-Al}_2\text{O}_3\text{-}$
1259 $\text{SiO}_2\text{-H}_2\text{O-TiO}_2\text{-Fe}_2\text{O}_3$ (KFMASHTO) proposed by White, Powell e Clarke (2002).
1260 Thermodynamics from plagioclase was according to Holland and Powell (2003).
1261 Epidote, cordierite, staurolite, and chlorite was according to Holland and Powell
1262 (1998). Garnet, biotite, and ilmenite-magnetite were according to White et al. (2007).
1263 Next, garnet and feldspar isopleths were calculated. A mean crustal density of $2.8 \times$
1264 10^3 kg/m^3 was used to calculate the geothermal gradient.

1265 The correlation between observed textures and microstructures (e.g., two
1266 distinct sillimanite habits, S-C fabric, granoblastic habit, to cite a few), coupled with
1267 homogeneous garnet crystals with pinitic rims are indicative of clockwise progressive
1268 metamorphism (Figure 11). Each episode will be characterized in detail in the
1269 subsequent section.

1270

1271 Figure 11 – Pseudo-section based on the whole rock composition of sample 16R2-
 1272 5B pre-deformational meta granitoid according to Tarney (1977). It has a composition
 1273 of Si60.47 Ti0.05 Al14.54 Fe₂+1.75 Fe₃+1.32 Mg0.62 Mn0 Ca0.48 Na1.61 K6.54
 1274 H12.66 O?. It consists of a leucosome with posterior metamorphic recrystallization
 1275 (see petrography section for more information). Its genesis coincides with the first
 1276 anatectic pulse at R1. To check the paragenesis of small fields, please consult
 1277 Supplementary Material 14.

1278 4.1 Metamorphic zones

1279 The rock has five distinct zones. Exothermic processes of high entropy
 1280 characterize the transition between zones (Spear, 1993; Fig. 14). Nonetheless, the
 1281 isograds may have a negative slope, characteristic of endothermic processes,

1282 mainly when processes of mineral-in or mineral-out occur in the system (e.g.,
1283 liquidus-in, garnet-in, biotite-out; Spear, 1993).

1284 The zones of pseudosection are, from low to high T: chlorite, biotite, garnet,
1285 cordierite, and sillimanite. The chlorite zone is characterized by < 400°C
1286 temperatures. The biotite zone ranges from 375°C to 800°C. In this model, due to its
1287 high amplitude, the biotite zone is not a useful PT index (Spear and Peacock, 1989).
1288 The garnet-in occurs above 0.35 GPa and 750°C, and the garnet-out in T conditions
1289 above 900°C. In a broad sense, the garnet zone occurs after the liquidus-in in the
1290 system. The liquidus increases the intergranular pressure, leading to garnet
1291 nucleation and growth (Ague and Carlson, 2013). Sillimanite zone occurs above
1292 550°C, and 1050°C, being partially dependent on pressure. There is no evidence of
1293 cordierite zone assemblage, nor relict structures related to it. Thus, the complex has
1294 not reached Barrovian type metamorphism during its evolution (Spear, 1993). All
1295 other zones occur and are related to specific recrystallization event.

1296 Table 2 – Summary of PT conditions of each recrystallization episode from MEBC as
1297 well as Depth and Geothermal gradient. Note that the geothermal gradient, even with
1298 the associated error, fits a collisional setting.

	P (GPa)	Depth (km)	T (°C)	Geothermal Gradient (°C*km ⁻¹)
R1	0.3-0.9	10.9	700	21-64
R2	1.05	38.3	800	21
R3	0.7-0.9	25.5	830-930	25-32
R4	0.3-0.9	10.9	700	21-64

1299 **4.2 Liquidus-in and first recrystallization episodes (R1)**

1300 This episode has a primary foliation and, when applicable, partially obliterated
1301 C-S fabric as characteristic textures. The former is result of a dominant pure shear
1302 condition; whilst the latter is a product of progressive strain circumstances (Passchier
1303 and Trouw, 2005). Nonetheless, both fabrics were partially obliterated during
1304 subsequences recrystallization episodes. Therefore, it is not recognizable whether
1305 the primary foliation cleavage obliterated the depositional strata or coincided with it.
1306 Additionally, R1 is coinciding with the first anatectic pulses, related to the formation of
1307 pre-deformational meta-granitoid. This specific rock is concordant with the primary
1308 paragneiss foliation and has direct evidence of ductile deformation generated before
1309 the static recrystallization. Thus, we interpreted that the first anatectic pulse might be

1310 generated around 700°C and between not less than 0.3 nor high than 0.9 GPa.
1311 These PT conditions generate a geothermal gradient ranging from 21 to 64 °C*km⁻¹,
1312 which might be expected by either arc or continental orogenic belts (Spear, 1993;
1313 Table 02).

1314 **4.3 Maximum pressure event (R2)**

1315 The maximum pressure event has two main petrographical textures. The
1316 granoblastic pattern on minerals (i.g. quartz, plagioclases, and so on) from
1317 paragneisses to tardi-deformational granite suggests that after the R1 event, the
1318 minerals stayed in a quasi-steady temperature x stress for long periods. Thereby
1319 generating *static recrystallization textures* (Passchier and Trouw, 2005). The static
1320 recrystallization directly affects the geometric interface of grains boundaries, and can
1321 obliterate any prior preferential mineral orientation created due to stress fields (Otani
1322 and Wallis, 2006); thus, justifying the lack of foliation proposed to R1. Additionally,
1323 the occurrence and quasi-homogeneity of garnets in almost all complex units mark
1324 the maximum pressure event. Quasi-homogeneous garnets are time-temperature
1325 dependent processes (=> 700°C; Spear and Peacock, 1989). The subtle
1326 compositional variation of garnets reflects not only long periods of crustal residence
1327 but also low uplifting rates (Jiang and Lasaga, 1990; Spear, 1991), as expected by
1328 collisional granulites (Bohlen, 2015). The garnet isopleth intersection suggests a
1329 crystal stabilization around 1.05 ± 0.05 GPa and 800°C, coinciding with the textures
1330 and proposed zones (Supplementary Material 15). These PT conditions generate a
1331 geothermal gradient of 21°C*km⁻¹, which is expected to continental orogenic belts
1332 (Spear, 1993; Table 02).

1333 **4.4 Metamorphic climax (R3) event and isothermal decompression**

1334 Sillimanite and fibrolite characterize the metamorphic episode R3. The
1335 presence of sillimanite attests high-grade metamorphism with associated partial
1336 melting, as expected in Granulite Terranes (Spear, 1993). Usually, this aluminum
1337 polymorph is associated with aluminum-rich sedimentary derived protolith (White et
1338 al., 2002). The two distinct sillimanite habits demonstrate environmental contrasts.
1339 We interpret that an isomorphous reaction with a preterit R2 kyanite probably formed

1340 the sillimanite with blade habit. Fibrolite, on the other hand, is usually related to either
 1341 anisotropy or process of a chemical reaction during the progressive strain
 1342 (Musumeci, 2002). The presence of fibrolite suggests reactions with the presence of
 1343 fluids and deformation (Digel et al., 1998; Musumeci, 2002; Vernon, 1979; Wintsch
 1344 and Andrews, 1988). The necessary fluid to fibrolite generation was available after
 1345 Biotite breakdown, that generates punctuate H₂O enrichment.

1346 As observed in thin section, fibrolite as well as ilmenite, alkali feldspar, and
 1347 melt are a product of the terminal reaction of Ti-rich biotite with garnet and
 1348 plagioclase (Equation 01).

1349

1350 Ti-rich Bt + Grt + Plag= Kspar + Grt + Sil + Ilm + Qtz + liq (Equation 01)

1351

1352 Alkali-feldspar, the by-product of Equation 01, has a strict composition that
 1353 suggests pressure of equilibrium around 0.8 ± 0.1 GPa and the temperature around
 1354 $880 \pm 50^\circ\text{C}$ (see Supplementary Material 15). These PT conditions generate a
 1355 geothermal gradient ranging from 25 to $32^\circ\text{C}\cdot\text{km}^{-1}$, which is expected to orogenic
 1356 belts exposed to high exhumation rates (Bohlen, 2015; Harley, 1989; Harlov, 2012;
 1357 Spear, 1993; Table 02). According to the modeled pseusection, temperatures close
 1358 to 900°C are characteristic of Biotite-out reaction, validating Eq. 01. Even after the
 1359 Biotite-out event, several biotites still occur in the analyzed sample. We interpret two
 1360 main possibilities: i) time-dependent terminal reactions between biotites and other
 1361 minerals, coinciding with fibrolite occurrence; ii) non-uniform temperature throughout
 1362 the complex, resulting in punctuate zones of dehydration, and thus, mineral absence
 1363 (e.g. biotite-out zone, "*incipient charnockitization*"), as expected in granulite terranes
 1364 exposed to partial melting (Frost and Frost, 2008; Grantham et al., 2012; Mendonidis
 1365 et al., 2015b; Mikhalsky et al., 2006).

1366 **4.5 Liquidus-out event and CO₂ rich liquidus(R4)**

1367 Post-deformational granitoid (1006 ± 13 Ma; Chemale Jr. et al., 2018); marks
 1368 the end-of Rodinia-forming orogen at MEBC. This unit indicates the very last
 1369 anatectic pulses that occurred in the complex. The lack of garnets, in opposition to
 1370 observed in the pre- and tardi-deformational granitoids, demonstrates that the melting
 1371 genesis occurred below the Garnet zone $<750^\circ\text{C}$. Still, it suggests that this lithofacies

1372 did not undergo high-grade metamorphic recrystallization events. The modeled
1373 liquidus-out isochore indicate a temperature between 700°C. The lack of garnets
1374 suggests temperatures below 750°C. Several textures corroborate to this
1375 observation. In post-tectonic granitoid, there are several occurrences of randomly
1376 arranged mineral (e.g., mostly alkali-feldspar) that suggest an isostatic stress field
1377 during their generation, in opposition to aligned minerals present in paragneisses,
1378 pre-, and syn- to tardi-deformational counterparts. These data demonstrate a change
1379 in the stress vector, probably related to the end of the collisional cycle. Igneous
1380 coarse-grained feldspars are associated with the late stage of crystallization, as a
1381 product of late-stage magmatic liquidus (Higgins, 1999; Johnson and Glazner, 2010).
1382 Bohlen (2015) suggests that there is a CO₂ enrichment related to last episodes of
1383 granulite terranes evolution, mostly associated with the final chapter of an orogenic
1384 cycle. CO₂ enrichment is a rule in Natal-Maud orogen. There are several occurrences
1385 of charnockites in Natal, Dronning Maud, and Falkland (Malvinas) Island that were
1386 interpreted as generated by CO₂ saturated liquidus (Grantham et al., 2012;
1387 Mikhalsky et al., 2006; Thomas et al., 1997 and references therein). Thus, we
1388 interpret that a late-stage magmatic liquidus with a probable high CO₂ content might
1389 generate coarse-grained feldspars present in post-deformation granitoid. However,
1390 specific studies to prove this assertion must be done. This CO₂ concentration, as well
1391 as the lack of garnets, and the preferential mineral lineation in post-deformational
1392 granitoid might be related to the end of the Stenian orogenic cycle at MEBC.
1393

1394 **5 DISCUSSIONS**

1395 Even with lack of regional mapping data (e.g., mineral lineation, rock fabrics,
1396 meso- and macro-scale structures, and so on), the lithostratigraphic history of a unit,
1397 and therefore, its tectonic environment, can be determined by using pseudosection
1398 analysis and PT trajectory through time interpretation (Bohlen, 2015; Girelli et al.,
1399 2018; Passchier and Trouw, 2005; Spear, 1993, 1993, 1991). MEBC consists of a
1400 polyphasic metamorphic terrain with at least two metamorphic cycles. The first cycle
1401 related to Rodinia forming orogen consists of a granulite-facies peak with a Stenian
1402 age (Chemale Jr. et al., 2018). It comprises recrystallization events R1 through R4,
1403 with a clockwise path. Granulite facies metamorphism with this trend is usually
1404 related to collisional tectonics (Harley, 1989; Harlov, 2012; Rudnick and Fountain,
1405 1995). The normal geothermal gradient for each episode suggests a continental
1406 orogenic belt evolution (Table 2). All episodes (i.g., sedimentary deposition R0, and
1407 recrystallization events R1 through R4) share their best age estimation with several
1408 units throughout Natal-Maud Belt. At MEBC, we interpret these events as caused by
1409 progressive regional metamorphism, related to the amalgamation of the Rodinia
1410 supercontinent (Roberts et al., 2015). Except when specified, all ages consist of U-
1411 Pb in zircon.

1412 The other events are related to retrograde low-grade metamorphism from
1413 other tectonic cycles. Retrograde metamorphism is tied to tectonic pulses dated from
1414 the Neoproterozoic-Paleozoic transition such as Pan-African, Pan-Antarctican, West-
1415 African Orogeny, among others (Pankhurst et al., 2006) or even younger events such
1416 as Gondwanides and Gondwana break-up (Chemale Jr. et al., 2018; Ramos et al.,
1417 2017). Those events will not be emphasized in this current study.

1418 **5.1 R0 – Sedimentary Basin evolution**

1419 The sedimentary deposition at R0 has detrital zircon with ages varying from
1420 1745 ± 10 (Peak 1), 1186 ± 4.8 Ma (Peak 2), and a Peak 3 concordant with
1421 metamorphic age, due to the tectonic context of the unit (Chemale Jr. et al., 2018).
1422 Peak 3 ages probably derived from Kaapvaal-Grunehogna craton. It is important to
1423 emphasize that either Peak 2 or Peak 3 group predominates, suggesting a juvenile

1424 source. Peak 2 ages occur in adjacent Mesoproterozoic terranes such as Haag
1425 Nunataks (1176 ± 76 Rb-Sr, Millar, and Pankhurst, 1987), East Antarctica (e.g.,
1426 Heimefrontfjella, ca. 1170 Ma leuco-gneisses; Jacobs et al., 2003). Additionally, in
1427 Natal Province, Thomas (2003) identified gneissic rocks with 1185 ± 15 Ma from
1428 Margate Terrane. Still, in Margate Terrane, there are garnet biotite gneisses with
1429 ages of 1169 ± 14 Ma (Mendonidis et al., 2015; Figure 12). Both rock units are
1430 related to arc magmatism (McCourt et al., 2006; Spencer et al., 2015b; Thomas,
1431 1989), generated due to a N-S (present coordinates) subduction system. It was
1432 hypothesized a back-arc basin southern of this arc (Grantham et al., 2012; McCourt
1433 et al., 2006; Mendonidis et al., 2015b; Mendonidis and Grantham, 2003; Spencer et
1434 al., 2015b).

1435 It is important to emphasize that there are several occurrences of
1436 metasedimentary gneisses at Heimefrontfjella, with kernel density probability plot
1437 similar with that obtained by MEBC paragneisses by Chemale Jr. et al. (2018; see
1438 Arndt et al., 1991; Johnston et al., 2001; Ksienzyk et al., 2007; Ross and Villeneuve,
1439 2003; Spencer et al., 2015). These metasedimentary gneisses were deposited in
1440 Sivorg back-arc basin, due to the erosion of Kottas arc rocks (Bauer et al., 2003b,
1441 2003a; Jacobs, 2009 and references therein).

1442 The integration of geochemical and provenance age data from MEBC
1443 paragneisses suggests that, by the time of deposition, the protoliths were close to the
1444 source area. The source area probably consisted of a volcanic arc, herein considered
1445 Maurice Ewing Bank (MEB) Arc. Orogenic dynamics, related to arc tectonics,
1446 exposed the source area. The arc-signature identified in paragneisses geochemistry
1447 herein presented also endorse this hypothesis, as well as the predominance of
1448 juvenile age zircons against others (see Chemale Jr. et al., 2018; Figure 13 - A). We
1449 interpret that MEBC paragneisses were deposited in the same back-arc basin system
1450 of Mzumbe-Margate, and Sivorg terranes.

1451 In the Falkland (Malvinas) Islands, there are no occurrences of such ages
1452 (Thomas et al., 2000; Figure 12). However, as postulated by Thomas et al. (1997),
1453 Big Cape Fm. is composed by amphibolites interspersed with paragneisses. The U-
1454 Pb in zircon ages of these two units are still unknown. The arc system of CMC, which
1455 generates “felsic orthogneisses” only developed during ca. 1120 Ma (Jacobs et al.,
1456 1999; Thomas et al., 2000, 1997).

1457 5.2 R1 and R2– Fold- and thrust-belt

1458 The R1 and R2 are herein interpreted as caused by a fold- and thrust-belt
1459 event. This event corresponds to a continent-continent collision and is related to the
1460 first anatectic pulses at ca. 700°C and high-pressure, as well as a recrystallization
1461 event around 1 GPa and 800°C. Negative ϵHf signatures (Chemale Jr. et al., 2018),
1462 protolith with a back-arc sedimentary deposition, followed by synchronous
1463 metamorphism with high-pressure and temperature, as well as syn-orogenic melting,
1464 validate this interpretation. The primary foliation, as well as the partially obliterated C-
1465 S fabric coincides with the deformation processes between R1 and R2. R2,
1466 according to our interpretation (e.g., static recrystallization, garnet homogenation,
1467 and so on), represents the orogenic climax. The R2 events is interpreted as
1468 generated by the 1068 ± 16 Ma ages obtained by Chemale Jr. et al. (2018), as the
1469 older syn- to tardi-deformational granitoid. This age coincides with the sinorogenic
1470 climax of Natal-Maud belt (ca. 1080-1020 Ma). As a result, there are several age
1471 occurrences found in *sensu latu* Natal-Maud belt (e.g., Natal, and Dronning Maud
1472 Land Terranes) and other near blocks (e.g., Falkland Islands, Agulhas Plateau, and
1473 Coats Land).

1474 In Margate Terrane, southernmost Natal terrane, several coinciding
1475 magmatism occurrences vary from ca. 1052 to ca. 1088 Ma (Mendonidis and
1476 Armstrong, 2016; Spencer et al., 2015 and references therein). Granulite facies
1477 metamorphism is usual, occurring at Margate Granite Suite (1044 ± 11 and $1034 \pm$
1478 26 Ma), and Leisure Bay Granulites (1047 ± 17 and 1046 ± 19 Ma; Mendonidis and
1479 Armstrong, 2016; Spencer et al., 2015). This dynamism also occurs at Mzumbe
1480 Terrane, where magmatic rocks ranging from ca. 1100 to 1045 Ma coincides with
1481 granulite facies metamorphism (Eglington et al., 2010, 2003, 1989). Tugela Terrane
1482 has compatible ages at Khomo Formation (1181 ± 126 Ma; Rb-Sr whole-rock) and
1483 Ngoye Granite (1067 ± 20 Ma; Barton, 1983; Figure 12). All these geological features
1484 led McCourt et al., (2006 and references therein) to interpret that Natal Province, by
1485 this time, as a thrust- and fold-belt environment due to the interaction between
1486 Kaapvaal craton and an unknown block.

1487 In Dronning Maud Land, there are several occurrences of synchronous
1488 magmatism and metamorphism with MEBC fold and thrust belt. Jacobs et al. (1998)
1489 identified a migmatite Augen gneiss with 1076 ± 14 Ma. Jacobs et al. (2003) and

1490 Bisnath and Frimmel (2004) also identified high-grade metamorphic overgrowth with
1491 respectively ca. 1080 and ca. 1070. Kirwanveggen has a migmatite Augen gneiss
1492 with 1074 ± 11 Ma (Jackson, 1999), as well as leucogranites with 1007 ± 57 Ma and
1493 orthogneisses with 1035 ± 18 Ma (Wolmarans and Kent, 1982). The metamorphism
1494 in the region is high grade and dated as 1081 ± 4 Ma by Jackson (1999) and $1061 \pm$
1495 14 Ma by Bisnath and Frimmel (2005). In Heimefrontfjella, several magmato-
1496 metamorphic units occur from ca. 984 to 1090 Ma (Jacobs, 2009 and references
1497 therein). Noteworthy is the occurrence of amphibolite facies metamorphism, dating
1498 as 1031 ± 27 , 1060 ± 8 , and 1062 ± 11 Ma (Arndt et al., 1991; Jacobs et al., 2003c).
1499 H.U Sverdrupfjella has several magmato-metamorphic units dated from ca. 1040 to
1500 ca. 1085 Ma (Grantham et al., 2008 and references therein). A paragneiss with 1044
1501 ± 47 Ma coincides with “D2” recrystallization event of Board et al. (2005); Also, there
1502 are zircon overgrowths dated as 1035 ± 21 Ma, being a product of “D3” deformational
1503 event. Generically, by this time, Western Dronning Maud Land terranes were
1504 involved in a complete fold- and thrust belt evolution (Bauer et al., 2016, 2003b).
1505 Additionally, a dextral transcurrent system, related to tardi collisional processes had
1506 already been developed (Bauer et al., 2016, 2003b).

1507 Microterranes that might be part of Natal-Maud orogens, such as Agulhas
1508 Plateau, Cape Meredith, and Coats Land, also have coinciding ages of
1509 magmatism/metamorphism. Allen and Tucholke (1981) had analyzed a quartz-biotite
1510 gneiss from Agulhas Plateau, using K-Ar in biotite, and obtained an isochron age of
1511 1105 ± 36 Ma for the unit. We interpret this data as metamorphic age of this unit. G1
1512 granodiorite and G2 mega crystal Augen gneiss from Cape Meredith Complex have
1513 ages ranging from ca. 1090 and 1067 ± 9 Ma, respectively (Jacobs et al., 1999).
1514 Chemale Jr. et al. (2018) already correlated the herein considered MEBC fold and
1515 thrust belt event with Cape Meredith Complex G1 and G2. In Coats Land,
1516 undeformed granophyre rhyolite and diabase from Coats Land were dated as $1078 \pm$
1517 7 Ma by Storey et al. (1994).

1518 The plethora of contemporary geological events points toward a regional
1519 orogenic climax. The event of ca. 1080 – 1040 Ma in which Natal and Dronning Maud
1520 Land are players, is related to Rodinia forming orogeny (Roberts et al., 2015). H.U.
1521 Sverdrupfjella, Kirwanveggen, Heimefrontfjella, Margate, and MEBC, by this time,
1522 stood right in the middle between Kalahari, “*East Antarctica*” craton collision (Bauer
1523 et al., 2003a) and an unknown cratonic mass (Cornell et al., 2006; McCourt et al.,

1524 2006). Jacobs et al. (2015) and references therein credited that the metamorphism
1525 and granitoid generation from DML are caused due to the collision between Kaapval
1526 and Coats Land craton. Loewy et al. (2011) hypothesized that Coats Land Craton
1527 and Grenville terrane, at Laurentia, have isotopic affinities; thus, being relatively
1528 close to each other by the time of their development. We interpret that MEBC, and
1529 thus its fold-and-thrust belt related metamorphism have strong age affinities not only
1530 to Western Dronning Maud Land (Bauer et al., 2003b), but also to Natal Province
1531 (McCourt et al., 2006). Cape Meredith Complex anatetic events could be related to
1532 MEBC collisional event; nonetheless, it is possible that the Falkland (Malvinas)
1533 basement represents a peripheric extension of collisional front (Figure 13 - B). The
1534 synchronous geological activity of Agulhas Plateau should be investigated in other
1535 studies to diminish the degrees of freedom about Rodinia evolution.

1536 **5.3 R3 – Orogeny exhumation and regional anatexis event**

1537 The R3 event marks the metamorphic climax in MEBC. A near-isothermal
1538 decompression curve, and therefore, a clockwise path diagnosis, characterizes this
1539 episode (Harley, 1989). We interpret that an over-thickened crust, followed by a rapid
1540 exhumation process might generate this condition (Bohlen, 2015; Harley, 1989;
1541 Rudnick and Fountain, 1995; Figure 13). Either erosion or rapid thinning, related to
1542 the tectonic exhumation, causes the decompression event (Harley, 1989).
1543 Thermodynamically, because of decompression at isothermal conditions, anatexis is
1544 a typical process, generating significant volumes of *liquidus*. MEBC shares the typical
1545 collisional granulites, which are felsic composition, correlation with paragneisses, and
1546 relation with upper crustal levels (Rudnick and Fountain, 1995). Additionally, MEBC
1547 fills the high-temperature granulite classification, being the first identified high-
1548 temperature-pressure granulite in Natal-Maud belt. We agree that the syn- to tardi-
1549 deformational granitoid age of 1032 ± 12 Ma, obtained by Chemale Jr. et al. (2018),
1550 represents this recrystallization event.

1551 There is a reduction in synchronous magmato-metamorphic ages from Natal-
1552 Maud belt related to this episode; however, the ages related to this event are
1553 associated with plutons of regional extent, and thus, a regional anatectic event. In
1554 Margate Terrane, Oribi Gorge has ages of 1049 ± 14 , 1037 ± 14 , and 1025 ± 8 Ma
1555 (Eglington et al., 2003; Spencer et al., 2015b; Thomas, 1989). On the contrary, the

1556 age of metamorphism is 1029 ± 8 (Eglington et al., 2003). Port Edward Pluton has
 1557 magmatic ages of 1034.4 ± 0.6 , 1039 ± 18 , and 1025 ± 8 Ma (Eglington et al., 2003;
 1558 Spencer et al., 2015b). Magmatic ages are ranging from 1042.6 ± 4.4 , and 1057 ± 27
 1559 Ma at Margate Suite. (Mendonidis and Armstrong, 2016; Mendonidis and Grantham,
 1560 2003). Still, in Margate Suite, there are cataloged metamorphic ages of 1044 ± 11
 1561 and 1037 ± 13 (Mendonidis et al., 2015b; Mendonidis and Armstrong, 2016). Mbazana
 1562 and Margate “D2” granites have ages of 1026 ± 3 , and 1042 ± 10 Ma (Grantham et
 1563 al., 2012; Mendonidis and Armstrong, 2016). Leisure Bay and Turtle Bay (mafic unit)
 1564 only have metamorphic ages that fit R3. They are 1047 ± 17 , 1046 ± 16 Ma from
 1565 Leisure Bay, and 1042 ± 7 Ma from Turtle Bay (Spencer et al., 2015b). There is only
 1566 one occurrence in Mzumbe Terrane from Fafa Pluton, which has 1037 ± 10 Ma as an
 1567 igneous placement age (Eglington et al., 2003; Figure 12).

1568 In Heimefrontfjella, there are several occurrences of monzonites (1045 ± 8
 1569 Ma), amphibolites (1048 ± 8 Ma), granodiorites (1045 ± 9 Ma; Arndt et al., 1991).
 1570 Also, Bauer et al. (2003) identified a dike with 1033 ± 7 Ma. Arndt et al. (1991)
 1571 identified that the rocks from Heimefrontfjella underwent a clockwise path, suggesting
 1572 continent vs. continent collision. In H.U. Sverdrupfjella, Jackson (1999), and Moyes
 1573 and Barton (1990) obtained an age of crystallization of 1050 ± 10 and 1015 ± 24 Ma
 1574 (Rb-Sr) for a leuco-pegmatite and an orthogneiss. Still in H.U. Sverdrupfjella, zircon
 1575 overgrowth with ca. 1044 and 1031 Ma were obtained and interpreted as the age of
 1576 peak metamorphism up to granulite facies (Board et al., 2005; Figure 12).

1577 There is no age occurrence from Cape Meredith Complex, nor Agulhas
 1578 Plateau, nor Coats Land. However, it is noteworthy that Coats Land and Agulhas
 1579 Plateau are still unknown territories, being only dated by old methods. For example,
 1580 of 12 recovered lithofacies at Agulhas Plateau, only two gave results consistent with
 1581 Mesoproterozoic. Coats land has an extensive area to be mapped; however, of
 1582 critical access (Gose et al., 1997).

1583 **5.4 The end of Rodinia-forming orogen at Maurice Ewing Bank (R4) and tardi-** 1584 **anatectic processes**

1585 The R4 event marks the end of Stenian-Tonian orogeny at MEBC. This event
 1586 is characterized by a retrograde metamorphism curve still on the liquidus-in zone,
 1587 result of an orogenic collapse at F2MT, as well as Natal-Maud belt (Figure 13). We

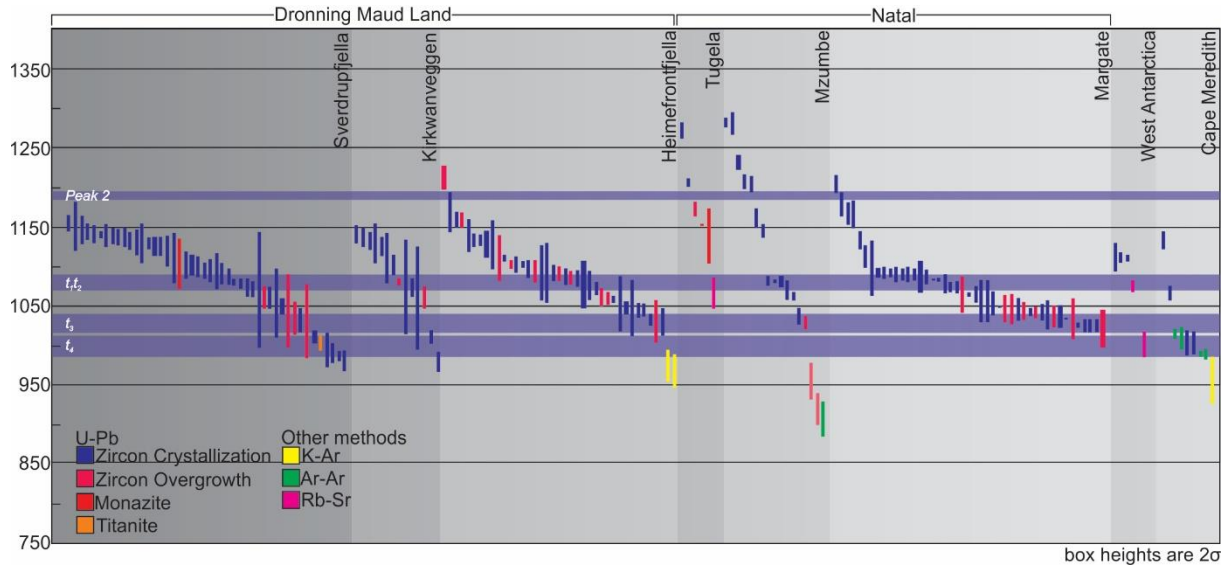

1588 agree that the post-deformational granitoid age of 1003 ± 16 Ma, obtained by
1589 Chemale Jr. et al. (2018), represents this episode. There is an increase in post-
1590 deformational ages from Natal-Maud belt. Additionally, rapid cooling processes are
1591 usual, being characteristic of the whole belt (Jacobs, 2009; Jacobs et al., 1999;
1592 Mendonidis et al., 2015b; Spencer et al., 2015b; Will et al., 2010, 2009). However,
1593 several portions of Dronning Maud Land, Shackleton Range, Natal, and Maurice
1594 Ewing Bank underwent thermal resetting due to posterior events (Jacobs, 2009;
1595 Jacobs et al., 1999; Spencer et al., 2015b; Will et al., 2010).

1596 In Natal Province, there is a dominant occurrence of low-grade
1597 metamorphism. In Mzumbe Terrane, there are occurrences, at Melville Thrust Zone of
1598 mylonitic Equeefa Dyke with Ar-Ar and K-Ar (Hornblende) ages of 988 ± 3 Ma. Their
1599 undeformed occurrences have ages of 1005 ± 4 Ma (Ar-Ar; K-Ar in hornblende). In
1600 the Jolivet, Shear zone occurs mylonitic amphibolites with ages of 1004 ± 2 and 1002
1601 ± 4 Ma (K-Ar, Ar-Ar in hornblende). In Lilani-Matigulu Shear zone, there are
1602 occurrences of gabbros with Ar-Ar in Hbl of 1003 ± 5 and 1009 ± 5 Ma (Jacobs et al.,
1603 1997, 1995; Figure 12).

1604 There are occurrences in Heimefrondfjella of ages is varying from 972 to 1019
1605 Ma. Jackson (1999) identified, at H.U. Sverdrupfjella and Kirwanveggen, a banded
1606 gneiss with 994 ± 22 Ma, a leucogranite with 990 ± 12 and a porphyritic granite with
1607 1011 ± 8 Ma. Moyes and Harris (1996), identified a late felsic dike with 1011 ± 8 Ma.
1608 In Sivorg Terrane, there are muscovites derived from pegmatites with ca. 987 Ma (K-
1609 Ar Muscovite). Ar-Ar in Muscovite, with ages of 987 ± 21 Ma suggests that some of
1610 the Heimefrontfjella rocks probably underwent a rapid cooling process (Jacobs et al.,
1611 1998; Figure 12).

1612 There are several age occurrences in Cape Meredith Complex, mostly related
1613 to G3 group. Leucogranites have crystallization ages of 1003 ± 14 Ma, while G3
1614 granite has an age of 1003 ± 16 Ma (Jacobs et al. 1999). Cape Meredith Complex
1615 rocks also underwent a rapid cooling process, as demonstrated by Ar-Ar in
1616 Hornblende in amphibolites with ages of 1015 ± 6 and 1009 ± 14 Ma, as well as Ar-Ar
1617 Muscovite ages of 989 ± 3 and 989.2 ± 3.4 Ma and Ar-Ar Biotite ages of 989 ± 7 and
1618 989 ± 6.5 Ma occurring at G3 granitoids (Jacobs et al., 1995; Figure 12).

1619 Eastin and Faure (1971) by using whole rock Rb-Sr had dated the rhyolite unit
1620 at Littlewood Nunataks, Coats Land, obtained 1001 ± 16 Ma. This data suggest that
1621 the Littlewood Nunataks may also played a role in Natal-Maud event (Figure 12).

1622

1623 Figure 12 – Ages of magmatism and metamorphism of Natal-Maud belt, including
 1624 West Antarctica + Coats Land and Cape Meredith Complex (Falkland-Malvinas
 1625 Islands) occurrences. Rb-Sr with high uncertainty was disregarded. Blue stripes
 1626 symbolize the events identified at MEBC. For a complete work reference, please
 1627 check Supplementary Material 16.

with R2 static recrystallization event at ca. 1060 Ma; C) Metamorphic climax,

1633

isothermal decompression and generation of MEBC Tardi-metagranitoids. D)

1634

Orogenic collapse, and post-deformational granitoids related to a extensional field at

1635

ca. 1000 Ma.

1636

5.5 Which terranes generate Natal-Maurice-Maud metamorphism

1637

MEBC is part of Natal-Maud belt; therefore, it constitutes a missing fragment

1638

of Kalahari Craton *sensu* Jacobs et al. (2008). However, the extent of Natal-Maud

1639

belt orogeny might be more significant than previously thought and is possibly related

1640

to Beattie-A magnetic anomaly, a subsurface structure that extends 1000 km E-W of

1641

South Africa (Beattie, 1909; Thomas et al., 1992). Quesnel et al. (2009) interpreted

1642

that granulite-facies mid-crustal rocks caused the anomaly. Lindeque et al. (2011)

1643 added that those rocks have a distinct north-dipping, relating them with Natal
1644 Province. Additionally, the authors suggest a south-dipping subduction zone during
1645 the Rodinia-forming orogen. Scheiber-Enslin et al. (2014), hypothesized that the
1646 Beattie-A's strong signal is due to the high susceptibility of granulite facies
1647 supracrustal rocks. The regional metamorphism of up to granulite facies is a
1648 distinctive characteristic of Natal-Maud belt, being identified at Natal Province
1649 (Cornell et al., 2006; Mendonidis et al., 2015b; Mendonidis and Armstrong, 2016;
1650 Mendonidis and Grantham, 2003; Spencer et al., 2015b; Thomas et al., 2003), Maud
1651 Belt (Bauer, 1995; Bauer et al., 2003a; Jacobs et al., 2015, 2003a, 2003c; Jacobs
1652 and Thomas, 1999; Ksienzyk et al., 2007), Falkland (Malvinas) Islands (Jacobs et al.,
1653 1999; Rex and Tanner, 1982; Thomas et al., 2000, 1997), MEBC (Chemale Jr. et al.,
1654 2018; Tarney, 1977; this work). Henceforth, we suggest that Beattie-A anomaly is a
1655 suture zone related to the collision between Kaapvaal and an unknown craton.

1656 We disagree with the actual consensus of Falkland (Malvinas) Island, and its
1657 180° rotation back to Rodinia amalgamation (e.g. (Jacobs and Thomas, 1999;
1658 Ksienzyk et al., 2007, and several references therein). There is actually no need to
1659 rotate Falkland (Malvinas) Island 180° to fit Falkland (Malvinas) Islands with regional
1660 data, nor limit their correlation with outcropping Mesoproterozoic units in Natal
1661 Province. Cape Meredith Complex can be considered as an eastward prolongation of
1662 Mesoproterozoic rocks that causes Beattie-A anomaly and as a northward
1663 prolongation of Coats-Patagonia Craton. By considering this assertion, Falkland
1664 (Malvinas) Islands structures such as metamorphic foliation, and mineral lineation
1665 coincides with those observed in Natal, thereby also demonstrating an SW-NE
1666 collision (Thomas et al., 1997, 1992). Also, Cape Meredith Complex has lithologies
1667 that are related to meta-volcanic-sedimentary arc (Jacobs et al., 1999; Thomas et al.,
1668 2000, 1997) that underwent collisional metamorphism. In specific, the Big Cape
1669 Formation is composed of layered gneisses, mostly consisting of amphibolites, felsic
1670 gneisses, calc-silicates, and metapelites (Thomas et al., 1997). The latter is
1671 composed by sillimanite, generated after a muscovite breakdown, suggesting high-
1672 grade peak metamorphism. This stratigraphic succession is usual in volcanic arcs,
1673 which partially justifies the Natal-Cape correlation. Jacobs et al. (1997) obtained
1674 1118 ± 8 Ma and 1135 ± 11 Ma (U-Pb in zircon) for the felsic gneisses and inherited
1675 zircons from G2 granites. However, the Margate-Vardeklattene arc was experiencing
1676 a partial melting event. The partial-melting event registered at Cape Meredith

1677 Complex is somewhat younger than its northern counterparts, only occurring at
1678 Maurice Ewing Bank due to peak metamorphism conditions. Recently, Chemale Jr.
1679 et al. (2018) and this work found evidences that MEBC and Cape Meredith Complex
1680 were indeed a single block in the Stenian-Tonian transition (F2MT). Schilling et al.
1681 (2017) pointed out that Deseado Massif, southern Patagonia, and Falkland
1682 (Malvinas) Islands still constitute a single block, named Patagonia-Malvinas terrane.
1683 Therefore, Deseado Massif, Falkland (Malvinas) Islands and MEBC were a single
1684 terrane since its generation, back to Meso-Neoproterozoic transition to Mesozoic.
1685 Any reconstruction should be aware of this fact.

1686 The continental margin that collided to Kaapval to generate Margate, Maurice
1687 Ewing Bank, Cape Meredith, and Beattie-A metamorphism and granitogenesis is still
1688 unknown. Nonetheless, there is a specific terrane that might fit this interpretation:
1689 The Patagonian Geological Province (Ramos, 2008; Ramos et al., 2004). Despite the
1690 lack of crystallization and metamorphism age from Mesoproterozoic, the province
1691 has T_{DM} ranging from 1.7 Ga to 854 Ma, as well as $^{87}Sr/^{86}Sr$, and ϵNd data suggest
1692 that Patagonian rocks derived from young Mesoproterozoic crust related with
1693 Rodinia-forming orogens (Pankhurst et al., 2006; Wareham et al., 1998). T_{DM} data
1694 from Martínez Dopico et al. (2011) derived from North Patagonian massif also
1695 supports this interpretation. Additionally, Schilling et al. (2008), suggest that xenoliths
1696 recovered close to North Patagonian Massif are the roots from Cuyania Terrane.
1697 Cuyania is currently interpreted as an allochthonous terrane related to
1698 Mesoproterozoic units in Laurentia (Ramos, 2010, 2008; Ramos and Naipauer,
1699 2014). Additionally, samples from the Deseado Massif gave depletion ages ranging
1700 from 1.34 to 2.11 Ga (Schilling et al., 2008). Recently, Mundl et al. (2015), by doing
1701 isotopic studies on mantle xenoliths, interpreted that rocks beneath Deseado Massif
1702 are similar to Natal-Namaqua belt rocks; thus, being directly related to the assembly
1703 of Rodinia. The rocks beneath the southernmost part of Deseado Massif has
1704 idiosyncrasies that point toward an Archean to the mid-Paleoproterozoic signature
1705 (Mundl et al., 2015; Schilling et al., 2008). Mundl et al. (2015) related them with the
1706 Shackleton Range in east Antarctica. Nonetheless, they might also be related to the
1707 still unknown Coats Land Block. We agree with the hypothesis postulate by Schilling
1708 et al. (2008), which propose that Deseado Massif is related to Falkland (Malvinas)
1709 Islands.

1710 During Stenian-Tonian transition, Patagonia was a missing-link between Coats
1711 Land, in Antarctica, and Grenville orogen, in North America. This interpretation aligns
1712 with data presented by Loewy et al. (2011) and this work, who identified similarities
1713 between Coats Land and Laurentia. Moreover, we propose that Patagonia's
1714 southernmost part is related not only with F2MT (Schilling et al., 2017) but also to
1715 Coats Land and Shackleton Range rocks (Will et al., 2010, 2009). The Northern
1716 Patagonia Massif , together with Cuyania-Chilenia terrane (Benedetto, 2004;
1717 Casquet et al., 2001; Kay et al., 1996; Mundl et al., 2015; Sato et al., 2004; Schilling
1718 et al., 2008; Thomas and Astini, 1996), is connected to Laurentia Llano Uplift (Nelis
1719 et al., 1989; Ramos, 2004; Sato et al., 2004). Coats-Patagonia craton has the
1720 characteristics to fit the regional geology found in the region. collided to Kaapvaal,
1721 generating the continent vs. continent metamorphism in Natal-Maud-belt. By
1722 considering this interpretation, Mesoproterozoic Patagonia, consisting from Chilenia-
1723 Cuyania rocks, as well as Northern and southern Massif basement consequently
1724 becomes part of Grenville orogeny (Martínez Dopico et al., 2011; Ramos, 2010;
1725 Ramos and Naipauer, 2014; Schilling et al., 2017, 2008).

1726

1739 **5.6 The printing of other tectonic cycles at MEBC**

1740 Several textures indicate a posterior low-grade retrograde metamorphism, as
 1741 already pointed out by Chemale Jr. et al. (2018) and Tarney (1977). The garnet
 1742 minerals usually have a late fluid phase (Pinite) in its edges. The substitution of
 1743 garnet by both chlorite and pinite, common in MEBC, is also an indication of
 1744 retrometamorphism processes. Albitization in plagioclases is conventional, related to
 1745 retrograde metamorphism in greenschist facies conditions (Moody et al., 1985 and
 1746 references therein) and might be related to the opening of the Rb-Sr system. Thus,
 1747 we interpret the whole rock Rb-Sr ages of 533 ± 65 Ma, obtained by Beckinsale et al.
 1748 (1977) in paragneisses, as generated by a greenschist facies retrometamorphism as
 1749 already suggested by Wareham et al. (1998), which associated the Rb-Sr resetting
 1750 with Panafrican-Panantarctican thermal anomaly field. Biotite substitution to
 1751 muscovite, chlorite, or mica with deficient lattices, as well as the presence of
 1752 saogenitic texture also foment this interpretation (Henry, 2005; Henry and Guidotti,
 1753 2002). The later suggests conditions of metamorphism similar to those observed in
 1754 Greenschist Facies (300-500°C; Shau et al., 1991). This temperature range is also a
 1755 requirement to open K-Ar in the rock system. Beckinsale et al. (1977), obtained ages
 1756 of 287 ± 7 and 399 ± 10 Ma (whole-rock K-Ar) in granites and paragneisses, relating
 1757 these results with “*several Paleozoic thermal reactivation events*” related to Argon
 1758 loss. We agree with Beckinsale`s interpretation.

1759 The late anchi-metamorphic to a diagenetic event cataloged in MEBC is
 1760 probably related with a Jurassic pre- to syn-rift episode at Falkland Plateau. Calcrete
 1761 paleosols (weathered paragneiss; Barker et al., 1977a) suggests a subaerial
 1762 exposition within dry conditions back to its development, and thus a regional
 1763 sequence boundary. Sediments deposited after this disconformity demonstrate a

1764 fluvial to lacustrine environment of Oxfordian age (Late Jurassic; Barker et al.,
1765 1977a), probably related to a syn-rift setting. These sediments have also been found
1766 in site 550 (de Graciansky et al., 1985) and seismically extended into the Falkland
1767 Plateau Basin (Marshall, 1994b). Similarly, syn-rift fluvio-lacustrine Jurassic
1768 sediments are also found at North Falkland Basin (Jones et al., 2019; Richards and
1769 Hillier, 2000), South Malvinas Basin (Foschi and Cartwright, 2016) and Agulhas zone
1770 (Stanca et al., 2019). It is prone that the same event that caused the rifting in those
1771 localities, also catalyzed the same process in MEBC during the Jurassic. In Falkland
1772 (Malvinas) Islands, there is also a record of rifting event of Jurassic age; however,
1773 not as sedimentation, but as mafic dykes placement. Mussett and Taylor (1994)
1774 dated an NWW, and NE dikes, using whole-rock Ar-Ar, and obtained 188, and 193
1775 Ma, respectively. Posteriorly, Stone et al. (2008), using whole-rock Ar-Ar, obtained an
1776 age of 179 Ma for NE dike. However, specific information such as timing and
1777 magnitude of Paleozoic through Mezozoic events still need more research.
1778

1779 **CONCLUDING REMARKS**

1780 The Maurice Ewing Bank Complex consists of igneous-metamorphic rocks
1781 that experienced polyphasic metamorphism related to at least two orogenic cycles. In
1782 a broad sense, we identified five lithofacies that represents a usual assemblage
1783 associated with collisional granulitic terranes. Due to high-grade conditions, the
1784 events of partial melting coexist with the metamorphism; thereby, generating igneous
1785 rocks pre-, syn-, tardi-, and post-deformational.

1786 The most abundant lithofacies consists of paragneisses. Their preterit detritus
1787 was deposited in a back-arc environment. The source area is widely linked with
1788 juvenile rocks derived from an exposed island arc. Paraderivated metamorphic rocks
1789 of similar age and Genesis are found either on Natal Province (mostly Margate) or
1790 Dronning Maud Land (mostly Kirvanveggen, Sverdrupfjella, and Heimefrontfjella).

1791 The first metamorphic cycle comprehends four episodes of recrystallization. It
1792 is interpreted as generated by the collision between the cratons of Kaapvaal and
1793 Coats-Patagonia. It is also correlated with the Rodinia forming events (R). The
1794 metamorphic evolution experienced by MEBC represents all normal orogenic cycles.

1795 We interpret that R1 (ca. 700°C, between 0.3 to 0.9 GPa) and R2 (800°C;
1796 1.05GPa) events as related to a fold-and-thrust belt evolution, product of
1797 compressional tectonics that had its climax at R2, around 1068 ± 16 Ma. Besides the
1798 paragneisses lithofacies, the pre-, and syn- to tardi-metagranitoids also represents
1799 this episode; we interpreted as caused by granulitization/partial melting, generated by
1800 collisional processes related to arc-continent, and mostly continent-continent
1801 collision. There are events of comparable magnitude and genesis in Mzumbe-
1802 Margate, Natal Province, as well as Sivorg-Vardeklattene, Dronning Maud Land.

1803 The event R3 is interpreted as caused by a thermometric decompression (ca.
1804 0.8GPa, and 880°C), which occurred around 1032 ± 12 Ma (age of syn-deformational
1805 metagranitoid). It represents the metamorphic climax related to the generator of
1806 Natal-Maud orogen. In a broad sense, it is associated with a regional exhumation
1807 event where there is an increase in geothermal gradient at the expense of decrease
1808 in pressure. Regions that experienced events of comparable conditions are
1809 characterized by possessing significant volumes of intrusive magma generated by
1810 partial melting. Thus, the diagnostic lithofacies of R3 is tardi-deformational granitoids.

1811 This decompression event is also correlated with large plutons located at Mzumbe-
1812 Margate, Natal Province, and Dronning Maud Land.

1813 The R4 event, occurred still at liquidus-in zone but below garnet zone,
1814 between 700-750°C. It occurred during 1003 ± 16 Ma, being correlated with post-
1815 orogenic processes. Thus, R4 diagnostic lithofacies comprises post-deformational
1816 granitoid. This event marks the end of the metamorphic cycle related to Rodinia
1817 forming orogens at MEBC. Pegmatites, coarse-grained dykes, and alkaline stocks
1818 have processes and genesis alike throughout Natal-Maud key players. Despite those
1819 terranes, there is also significant volumes of partial melting related to Cape Meredith
1820 Complex, Falkland-Malvinas Islands.

1821 The MEBC, due to geological likelihood, constitute a parcel of Kalahari Craton.
1822 During its generation and evolution, the complex stands between the Margate and
1823 Heimefrontfjella terranes. The collisional event, consistent with those events that
1824 occurred in the Antarctica (e.g., Western Dronning Maud Land) and South Africa
1825 (e.g., Natal Province) counterparts, is interpreted as caused by the interaction of
1826 Kaapvaal and Coats-Patagonia margins. The latter has geological characteristics that
1827 match with Grenville orogen, located in Laurentia. Henceforth, MEBC is not only part
1828 of Natal-Maud Belt, but also constitutes a crucial role in the understanding of
1829 intercontinental Grenvillian orogeny.

1830 Several indicators suggest retrometamorphism up to greenschist facies,
1831 correlated with the second metamorphic cycle in which MEBC underwent. The
1832 retrometamorphism experienced by MEBC is related to Rb-Sr, and K-Ar isotopic
1833 system reset. The former occurred during 533 ± 65 Ma, being interpreted as
1834 generated by far-field anomalies associated with Panantarctican-Panafrican
1835 orogenies. Neoproterozoic metamorphic/granitogenesis events are widely found not
1836 only in East and West Antarctica but also as outcropping basement of Cape Fold-
1837 Thrust Belt and Patagonia. The closure of the K-Ar system occurred in two stages,
1838 287 ± 7 and 399 ± 10 Ma, being correlated with “several reactivations during the
1839 Paleozoic.”

1840 There are events of recrystallization below 300°C. We interpret them as
1841 generated due to the thermal instability catalyzed by Mesozoic rifting. Two rifting
1842 events occur in or close to the MEBC, with Jurassic and Cretaceous age.
1843 Nonetheless, their timing and reasons are yet uncomprehend. Therefore, we suggest
1844 a profound study in the retrometamorphic-anchimetamorphic processes in MEBC to

1845 fathom the interplay between low-temperature metamorphism-diagenesis and the
1846 evolution of Falkland-Malvinas Plateau.

1847 This work shed light between Mesoproterozoic terranes of Natal-Maud, the
1848 interaction with adjacent terranes, including Patagonia-Coats Land and Grenville
1849 orogen. However, there are still several questions that remain unresolved, such as i)
1850 the role of Haag Nunataks and Agulhas Plateau in the Mesoproterozoic; ii) Is the
1851 easternmost portion of Maurice Ewing Bank Terrane part of Paleozoic-Archean crust
1852 of Kaapvaal Craton? iii) What is the evolution of the Falkland Plateau and what
1853 implications does it have to the positioning of Falkland (Malvinas) Islands during
1854 Mesozoic? iv) The movement of the Patagonia Province, since its generation, back to
1855 Mesoproterozoic until the present configuration.

SUPPLEMENTARY MATERIAL

SUPPLEMENTARY MATERIAL 1 – SAMPLING AND LOGGING INFORMATION

Table 3 – Sampling and logging information of DSDP Site 330. Lithofacies according to this work. Bold letter in classification refers to classification according to Tarney (1977). Italic letters in classification refers to classification according to this work.

Core	Section	Interval	Code	Geochemistry Tarney + Farid	Lithofacies	Classification	Thin Section A	Thin Section B Code
15	2	130-132	1		Peat / Coal / Black Shale			
15	2	132-135	2		Organic medium sandstone			
15	2	135-137	3		Peat / Coal / Black Shale			
15	2	137-141	4		Medium Sandstone w/ pebbles			
15	2	141-143	5		Peat / Coal / Black Shale			
15	2	143-145	6		Peat / Coal / Black Shale			
15	2	145-150	7		Medium Sandstone w/ pebbles			
16	1	26-31	1	#01 (18-22)	Weathered Paragneiss	Calcite-impregnated metasedimentary gneiss		
16	1	31-37	2	#02 (30-38)	Weathered Paragneiss	Calcite impregnated metasedimentary gneiss with large poikilitic calcites		
16	1	40-46	3		Weathered Paragneiss			
16	1	46-53	4	#03 (52-55)	Syn- to tardi-deformational granite	Coarse K-feldspar-rich pegmatitic vein (S2)		
16	1	55-58	5		Weathered Paragneiss			
16	1	58-61	6		Weathered Paragneiss			
16	1	63-69	7		Weathered Paragneiss			

16	1	69-77	8	#04 (71-78)	Weathered Paragneiss	Quartz-rich granular gneiss

**SUPPLEMENTARY MATERIAL 3 – COMPARISON BETWEEN PETROLOGICAL
INTERPRETATION FROM TARNEY (1977), CHEMALE ET AL. (2008) AND THIS WORK**

Table 5 – Comparison between petrological interpretation

Tarney (1977)	Chemale Jr. et al (2008)	This work
Metasedimentary Gneiss	Granulite Paragneiss	Paragneiss
Deformed Pegmatitic Gneiss	Not observed	Pre-deformational Metagranite
Granite Pegmatite T1	Pink granite	Tardi-deformational Granitoid
Granite Pegmatite T2	Post-kinematic pink granite	Post-deformational Granite
Microsyenite Intrusion	Not observed	Paragneiss
Thin Basic Veins	Biotite layer	Melanosome

SUPPLEMENTARY MATERIAL 4 - MICROTTECTONICS

Figure 15 - Main textural and mineral features observed in the studied thin section. **A** – 16R2-10A (0.63-0.67m) Contact between the Syn-to tardi-deformational granitoid and Paragneiss. Note the trachytic texture, according to I_{min} . Also notice the granoblastic texture of quartz in both rocks, demonstrating time span of static recrystallization. Between the lithological interface, that is, the zone of weakness, it was generated a cataclastic zone with horse-tailing structures. **B** – 17R2-14A (0.87-0.96m) Evidence of dynamic recrystallization – Pinning and window indicative of grain boundary migration (GBM), and therefore high-temperature processes; **C** – 17RCC-03 (0.34-0.35m) – Paragneiss - Chessboard and deformation lamellae microtextures, demonstrating the momentum of overlapping during the first episode of progressive deformation in quartz crystals. The former is indicative of superposing factors such as high temperature, strain rates, differential stresses, and water content in either crystal lattice or grain vs. grain interface. The latter is indicative of a progressive attenuation of those factors. The overlap of those contrasting features suggests processes of retrometamorphism that mitigate the crystal recovery. **D** - 17RCC-03 (0.34-0.35m) – Paragneiss – Bulging (BLG) and undulose quartz extinction. superposing of low-

temperature/low-grade dynamic recrystallization microstructures; **E** – 17R2-14B (0.87-0.96m) – Foliation planes of paragneisses and C-S fabric, suggesting a progressive deformation that after the generation of an S_n plane, it was generated an oblique foliation S_{n+1} , followed by an event of static recrystallization; **F** – 16R2-01B (0.00-0.06m) Weathered Paragneiss generated after the nucleation and homogenisation of garnet. The highly fractured porphyroblast type δ has an eye-shaped pattern, indicative of high strain rates in a dextral motion. The presence of truncated biotite fishes also corroborates to a dextral movement, with the shearing band near the interface of porphyroblast mantle. **G** – 16R2-08A (0.50-0.56m) - Garnet porphyroblasts amalgamated within the lineation plane. This feature suggests that the Grt crystals superimposed each other, after the homogenization event and during the event of metamorphic climax. Probably, this fabric is related to a transtensional stress regime associated with the R3 episode; **H** – 16R2-08A (0.50-0.56m) Isomorphic bladed sillimanite aligned according to I_{min} ; **I** – 16R2-08A (0.50-0.56m) fibrolite product of reaction Biotite + Garnet = Ilmenite+Fibrolite+Alkali Feldspar+Quartz+Water. Note that the Grt porphyroblast is partially consumed, whilst the Bt is entirely absent. This *in-situ* reaction validates the modeled pseudosection; **J** – 16R2-01B (0.00-0.06m) Idiomorphic Tabular tourmaline porphyroblast related to post-deformational events; **K** – 17R2-14A (0.87-0.96m) Sagenitic texture in Biotite, which represents low-grade metamorphism, typical of medium to superior green-schist facies. **L** – 17R2-13B (0.79-0.87m) Ruptile regime and cataclasis evidence – the presence of Riedel Shear indicator in quartz porphyroblast, suggesting a dextral sense motion during ruptile-ductile episodes. Mff - microscopic feather features; **M** – 17R2-13B (0.79-0.87m) Extensional vein en-echelon filled by a tardi calcite mineral, with distinctive pressure twinning, suggesting a dextral shear sense. Note in the superior right corner the presence of twin pair, suggesting deformational processes in the supracrustal regime. In the superior left corner, there are antithetical fractures in Qtz crystals, cogenetic with those of “M,” also indicative of dextral sense; **N** – 17R2-14A (0.87-0.96m) Bookshelf microtexture in pygmatic Cal vein, indicating a progressive dextral deformation even in tardi-deformational low-temperature processes.

SUPPLEMENTARY MATERIAL 5 – X-RAY DIFFRACTOMETRY (XRD) OF MELANOSOME.

We made x-ray diffractometry (XRD) whole-rock analysis at Instituto de Geociências da Universidade de Brasília (UnB) in sample #16R2-11 to identify whether there is the presence of expansive clays or not. The sample was pulverized and compacted on the glass section. After the XRD analyses were conducted on a Rigaku Ultima IV coupled with DETEX, using $\text{CuK}\alpha$ radiation ($\lambda = 1.5418 \text{ \AA}$), a Be filter, a voltage of 35 kV, and a current of 15 mA. The scan speed was $2^\circ/\text{min}$, with steps of 0.05° , and the 2θ interval between 3° and 80° .

The minerals identified using this technique agree with the petrographical description of the melanosome. We interpret the peak in intensity at $d=10$ and $d=3.34$ as characteristic of biotite. Rutile is also present, with two distinct peaks at $d\approx 3.3$, and $d=1.66$. These paragenesis fits the sagenitic texture, characteristic of this lithofacies. Additionally, chlorites (i.g. corrensite) were also identified, with two peaks at $d=31.49$ and $d=14.15$. Thus, we suggest that the green-mineral pointed out by Tarney (1977) is corrensite. There are two late mineral phases in this lithofacies: i) calcite; ii) kaolinite. Their presence suggests low-temperature processes (Figure 16).

Figure 16 – RX Diffractogram of sample #16R2-11, which consists of melanosome lithofacies.

SUPPLEMENTARY MATERIAL 8 – TOURMALINE CHEMICAL DATA

Tourmaline group minerals were analyzed using the software WinTCal (Yavuz et al., 2014). They were normalized to have either 15 cations at T + Z + Y position or the sum of OH + F + Cl=4. The Fe³⁺ content was estimated according to the normalization to O_{24.5} and stoichiometric calculation of H₂O content made on software.

All crystals fit the alkaline tourmaline zone with two distinctive populations (hydroxy- and fluor). They have a significant amount of ^YMg²⁺ in comparison with other elements that can fit Y-site. Also, there is an exotism of the allocated element in the X-site (i.g. K¹⁺). According to Henry et al. (2011) classification scheme they are classified as Potassium Rich (Fluor)-Dravites (Figure 17).

Figure 17 - Tourmaline classification according to Henry et al. (2011). A – Ternary diagram of Tourmaline Primary Group, according to the element that fits the X-site vacancy. Note that K¹⁺ occupies the vacancy, instead of Na¹⁺. B – Ternary diagram of tourmaline species, according to the element that fits the W-site vacancy. Note two distinct populations: OH¹⁻ rich near the crystal center, and F¹⁻ near the crystal rim. C- Ternary diagram of alkali elements that fit the Y-site. Note that the analyses have a trend from Mg-rich nucleus to Fe-rich borders.

A variety of environments can generate tourmalines. The tourmaline crystals have a wide stability range using PT, fluid composition, and whole rock composition (van Hinsberg et al., 2011). Here, we interpret the tourmaline as generated during the post-kinematic event (e.g., the post-kinematic blade shape of its crystals). Additionally, it is identifiable that the tourmaline has a metamorphic origin; thereby, being related to metapelites, Ca-poor metapelites, and metapsamites (Figure 18 - A e B). There is no relationship with the tourmalines and greisenization processes or contact metamorphism (Figure 19 - C). Thus, the tourmalines were generated by tardi-fluid-rich metamorphism. This data suggests that,

by the time of tourmaline generation, the metamorphism generated the granitogenesis, not the opposite.

Figure 18 - Tourmaline classification. A and B) Ternary diagrams proposed by Henry and Guidotti (1985) to predict the geotectonic environment in which the tourmaline were generated. Legend: A) 1–Li-rich granitoid pegmatites and aplites; 2–Li-poor granitoids and their associated pegmatites and aplites; 3–Ferric iron-rich quartz-tourmaline rocks (hydrothermally altered granites); 4–Metapelites and metapsammities coexisting with an Al-saturating phase; 5–Metapelites and metapsammities not coexisting with an Al-saturating phase; 6–Ferric iron-rich quartz-tourmaline rocks, calc-silicate rocks, and metapelites; 7–Low-Ca meta ultramafics and Cr, V-rich metasediments; B) 1–Li-rich granitoid pegmatites and aplites; 2–Li-poor granitoids and associated pegmatites and aplites; 3–Ca-rich metapelites, metapsammities, and calc-silicate rocks. 4–Ca-poor metapelites, metapsammities, and quartz-tourmaline rocks; 5–Metacarbonates; 6–Metaultramafics. C) Binary diagram proposed by Pirajno and Smithies (1992) to estimate the proximity with a granitic source, based on major elements. Modified from Yavuz et al. (2014).

SUPPLEMENTARY MATERIAL 10 – GARNET DERIVATION ACCORDING TO ITS CHEMISTRY

Figure 19 - Ternary Diagrams utilized by Krippner et al. (2014) to discriminate which rock the garnets derived from a) Diagram proposed by Wright (1938). Maurice Ewing Bank Garnets fall into granite and granites pegmatites garnets.

b) Diagram proposed by Mange and Morton (2007) where A - High-grade rocks, mainly granulite or charnockites and igneous intermediate or felsic rocks; B – Metasedimentary rock that underwent to amphibolite facies; Bi – igneous intermediate or felsic rocks; Ci – high-grade metamorphic mafic rocks; Cii – High-Mg rocks such as metapyroxenites and metaperidotites; D – metasomatic rock, very low-grade rocks and calc-silicates from ultra-high-temperature metamorphism. Note that garnets from MEBC fall into either field A or B, being related to granulites or igneous intermediate or felsic rocks.

c) Diagram proposed by Aubrecht et al. (2009). A – High pressure terranes and ultra-high pressure terranes; B – Eclogite or Granulite facies rocks; C – Amphibolite rocks. C1 – from upper amphibolite to granulite transition; C2 – Amphibolites but also blue-schists, skarns, serpentinites, and igneous rocks. The lithologies where garnets came from are: 1 – ultra-high eclogite terranes or peridotites; 2 – high-pressure eclogite and high-pressure mafic granulite; 3 – intermediate to felsic granulite; 4 – garnets from gneisses of upper amphibolite to granulite facies; 5 – garnets from amphibolites of upper amphibolite to granulite facies; 6 – garnets from gneisses of upper amphibolite facies. Note that MEBC garnets fall into field 4, suggesting a gneiss as host rock, metamorphosed in upper-amphibolite to granulite facies metamorphism.

d) Diagram proposed by Teraoka et al. (1998, 1997). L – low-grade rocks; la – intermediate grade rocks (amphibolite facies); H – high-grade rocks; lg1 and lg2 - intermediate grade rocks (granulite facies); E – eclogites, G – granodiorites. Note that garnets fall into granulite facies rocks.

e and f) Diagram proposed by Suggate and Hall (2014). Note that either in e or f, garnets do fill intermediate facies derivatives.

Figure 20 – Reaction boxes from Pseudosection analyses.

SUPPLEMENTARY MATERIAL 15 – GARNET AND ALKALI FELDSPAR ISOPLETS

Figure 21 – Garnet isopleths. A - X_{Fe} isopleths, demonstrating a high-temperature inverse proportionality with almandine series; B - X_{Mg} component, demonstrating a P x T direct proportional relationship with pyrope series. C - X_{Ca} suggesting either an inverse proportion between grossular series. Numbers represent recrystallization events. Arrows represent a simplified P x T trajectory.

Figure 22 – Alkali-feldspar isopleths. A – X_{FK} ; B – X_{Ab} ; C - X_{An} .

Table 16– Alkali feldspars close to Bt-out reaction identified in #16R2-08.

SUPPLEMENTARY MATERIAL 16 – AUTHOR REFERENCES

We made the Natal-Maud Belt age distribution chart using the software Isoplot (Ludwig, 2012). The ages from Agulhas Plateau are according to Allen and Tucholke (1981). Coasts Lands and West Antarctica ages are according to Eastin and Faure (1971), Gose et al. (1997), Millar and Pankhurst (1987), and Storey et al. (1994). Meredith Complex ages are according to Jacobs et al. (1999), and Rex and Tanner (1982). The ages from Sverdupfjella Terrane are according Bisnath and Frimmel (2005), Board et al. (2005), Grantham et al. (2008), Groenewald et al. (1995, 1991), Harris (1999), Harris et al. (1995), Jackson (1999), Moyes et al. (1993), Moyes and Barton (1990), and Moyes and Harris (1996). The ages from Kirwanveggen Terrane are according Bisnath and Frimmel (2005), Groenewald et al. (1995), Harris (1999), Jackson (1999), and Wolmarans and Kent (1982). Heimefrontfjella ages are according to Arndt et al. (1991), Bauer et al. (2003a, 2003c, 2003b, 2016), Gose et al. (1997), Groenewald et al. (1995), Jacobs et al. (1996, 2003a, 2003c, 2003b), and Jacobs (2009). The ages from Natal Province are according Barton (1983), Cornell and Thomas (2006), Eglington et al. (2010, 2003), Evans et al. (2007), Grantham et al. (2012), Harmer (1979); Jacobs and Thomas (1996), Johnston et al. (2001); Mendonidis et al. (2015, 2002); Mendonidis and Armstrong (2016, 2009), Spencer et al. (2015), Thomas (1989), Thomas et al. (2003, 1996), and Thomas and Eglington (1990).

FIM DO MANUSCRITO

1 CONCLUSÕES

2 • As rochas do embasamento de Maurice Ewing Bank consistem de um
3 complex formado por rochas metamórficas polifásicas e contrapartes ígneos
4 intrusivos.

5 • Cinco litofácies magmato-metamórficas foram descritas em detalhe,
6 representando uma assembléia comum de terrenos granulíticos colisionais, onde
7 processos ígneos e metamórficos coexistem em uma intrínseca relação.

8 • Mesmo com a carência de elementos de mapeamento, os dados
9 obtidos e interpretados coincidem com dados de terrenos adjacentes como Província
10 Natal (majoritariamente Margate) e Dronning Maud Land (majoritariamente
11 Kirvanveggen, Sverdrupfjella e Heimefrontfjella).

12 • Os protólitos da litofácies paragneiss foram depositados próximos a
13 fonte, em um context de *back-arc*. Os detritos derivaram de rochas juvenis expostas
14 devido a tectônica collisional em uma elongação do arco meta-vulcanossedimentar
15 de Margate-Sivorg.

16 • A primeira fase de recristalização, relacionada com os eventos
17 Grenvillianos, é dividida em 4 episódios de recristalização / deformação. A evolução
18 experienciada pelo MEBC contempla o espectro esperado de um ciclo orogênico.

19 • Os eventos Rodínia 1 (R1) e R2 são relacionados com um episódio de
20 dobramento e cavalgamento Gerado pela colisão de duas massas cratônicas. Esse
21 evento gerou os granitos pré- e sin-deformacionais. Mzumbe e Margate, na província
22 de Natal, e Sivorg-Vardeklettane, em Dronning Maud Land, também registraram
23 eventos de gênese similar, relacionado com granulitização e geração de fusão
24 parcial.

25 • O evento R3 é interpretado como o climax metamórfico, chegando a
26 fácies Granulito. Entre R2 e R3 há um episódio de descompressão termométrica,
27 interpretada como gerada por exumação tectônica. Como resultado da
28 descompressão, granitóides sin- a tardi-deformacionais, produto de expressivos
29 volumes de fusão parcial, são a litofácies característica. Este evento
30 descompressivo também é registrado, através da ocorrência de grandes plutons em
31 Mzumbe-Margate e Dronning Maud Land.

32 • O evento R4 é correlacionável com processos tardi-anatéticos e possui
33 como litofácies característica os granitóides pós-deformacionais. Este evento marca
34 o fim da orogênese formadora do Rodínia no MEBC. Nas regiões adjacentes há
35 diversas ocorrências de pegmatites, diques de grão-grosso e stocks alcalinos
36 interpretados como gerados por processos pós-tectônicos.

37 • Portanto, nós interpretamos que MEBC é originalmente derivado do
38 cráton de Kalahari, estando entre os terrenos de Margate e Heimefrontfjella da
39 Província de Natal e Maud Land, respectivamente.

40 • Nós propomos que as duas massas cratônicas que geraram o evento
41 collisional formados da orogenia Natal-Maud consistiu do cráton de Kaapvaal e
42 cráton de Coats-Patagonia. Em especial, o cráton de Coats-Patagonia representava
43 uma extensão da orogenia Grenville, localizada no Laurentia. Portanto, MEBC é não
44 somente parte do cinturão de Natal-Maud, mas também o cinturão Natal-Maud é
45 parte da orogenia Grenville.

46 • O segundo ciclo tectônico é relacionado com o resetting dos sistemas
47 Rb-Sr e K-Ar nas rochas de MEBC. De maneira geral, o complex possui evidências
48 que apontam a eventos de retrometamorfismo na fácies xisto-verde. O reset do
49 Sistema Rb-Sr é interpretado como Gerado por anomalias térmicas *far-field*
50 relacionadas com a orogenia Ross, amplamente distribuído nos blocos da Antártica
51 Leste e Oeste, além do embasamento aflorante do cinturão de Cabo e Patagônia. O
52 reset do Sistema K-Ar é interpretado como produto de “diversas reativações termais
53 durante o Paleozóico”.

54 • Há eventos de recristalização relacionados com temperaturas abaixo
55 de 300°C e , como consequencia, regime rúptil. Nós os interpretamos como produto
56 da instabilidade termal ocasionada por eventos de rifteamento Mesozóico. Nas
57 adjacências de MEBC há um evento extensional do Jurássico e um do Cretáceo; no
58 entanto, os processos catalizadores e seus *timings* ainda não são compreendidos.

59 • Ainda há diversas questões que mantêm-se não resolvidas: i) Qual o
60 papel de outros micro-blocos, tais como Haag Nunataks e Agulhas Plateau no
61 Mesoproterozóico? Seria o extremo leste do alto de Maurice Ewing Bank
62 pertencente a uma crosta Paleoproterozóica-Arqueana do cráton de Kaapvaal? iii)
63 Qual a evolução do Platô de Falkland e quais as implicações sobre o
64 posicionamento das Ilhas Falkland (Malvinas) durante o Mesozóico? iv) Qual a

65 cinemática da Província da Patagônia entre sua geração, no Mesoproterozóico e
66 posicionamento próximo ao atual, no Mesozóico?
